PATERNOSTER ROW.

ADVERTISEMENT.

THIS CYCLOPÆDIA has been prepared with the express desire to carry out the most important object connected with the Great Exhibition—that of regarding it as an instrument of education. Here, *at a rate of unequalled cheapness,* will be found *a full explanation of every subject that can suggest itself to the enquiring visitor.*

The information thus given is brought up to the *very latest accession of knowledge.* THE SCIENTIFIC DETAILS, avoiding as much as possible all embarrassing technicalities, aim at precision and accuracy. The GEOGRAPHICAL ARTICLES exhibit the characteristics of the Industry of All Nations, not only as to large States, but as regards Cities and Ports ; and these particulars are founded upon the best and most recent statistical information. The PROCESSES of MANUFACTURES are described in most cases from actual observation, and are ILLUSTRATED BY A SERIES OF ENGRAVINGS which embrace the *entire range of Factory production.*

It may be affirmed without presumption that the Visitor to the Exhibition, by reference to the "Cyclopædia of the Industry of all Nations," will be able to regard that wondrous collection, not with a vague curiosity, but an intelligent appreciation. With the Shilling Catalogue to accompany his visits, and the Cyclopædia to direct him, he may accomplish much that is proposed to be attained by Courses of Lectures. Take an example :—

A Visitor purposes to devote a morning to the department of *French* Industry. He refers to the Cyclopædia—perhaps as follows :

France. This article contains a brief general view of all the staple industries of that country.

But the catalogue is headed France and Algiers. He turns to *Algiers* in the Cyclopædia, and finds a similar view of its industry.

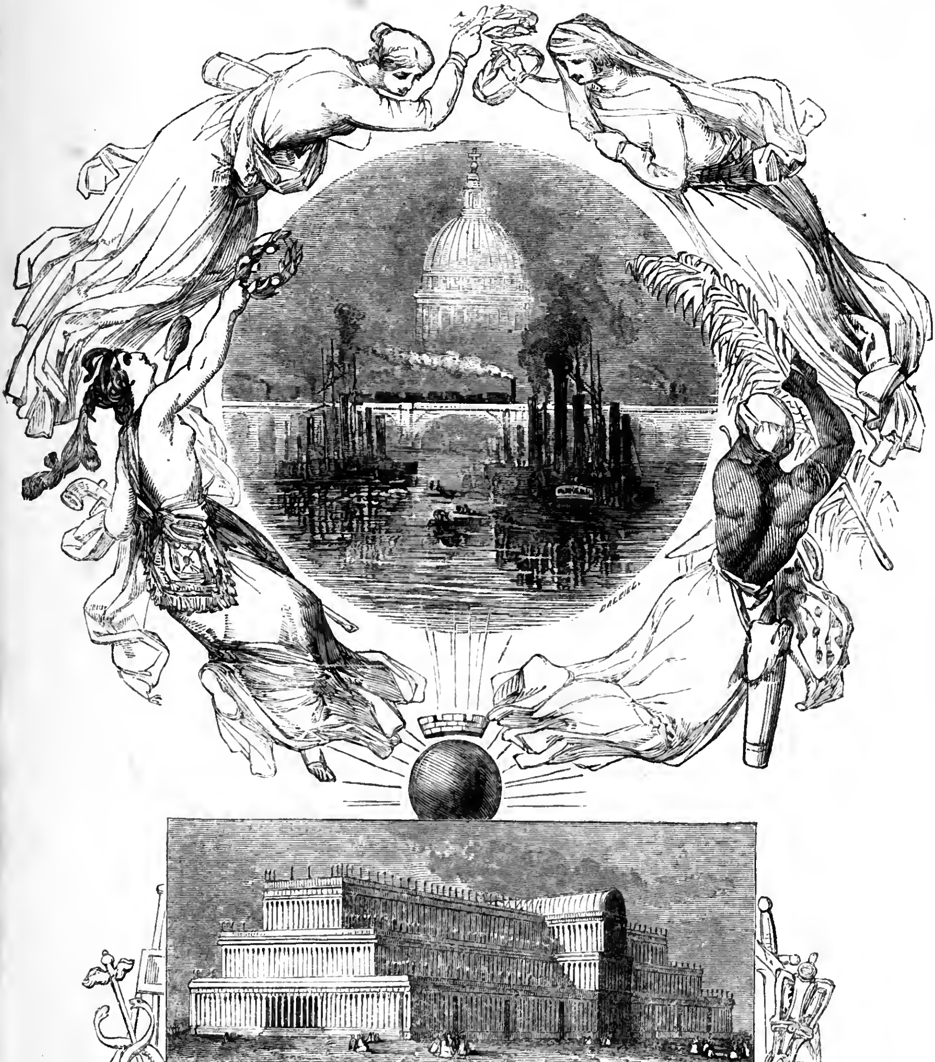
The first article in the *French Catalogue* is as follows :

> "1. Adolphe, C. Manufactory, *Mulhouse* (Haut Rhin) and at M. Grebin's, 8, Rue de la Bourse, *Paris.*—Pieces of *silk* and *woollen damask,* wrought by *Jacquard looms.*"

The *words* above marked in Italic indicate the nature of the information which will be found in the *Cyclopædia of Industry* under those heads. He will there learn what is the peculiar industry of Mulhouse (*Mulhausen*)—what the character of the trade of Paris—the processes of silk and woollen manufacture generally, as well as of damask weaving, and the peculiarities of the Jacquard loom. In addition, by turning to the ENGRAVINGS, he will see the processes of *Silk Manufacture,* No. 29 ; and of *Woollen,* Nos. 36 and 37.

It may perhaps be necessary to add that the "Cyclopædia of the Industry of all Nations" IS NOT A TEMPORARY WORK, or one of limited utility. It will be found as useful in the Merchant's Counting-house as in the Mechanics' Institute—as interesting in the School-room as in the Crystal Palace.

This Cyclopædia has been *founded* upon materials which are the copyright of the Publisher ; but these materials have been condensed or added to, with reference to the immediate purpose of the work,—and a great number of original articles have been introduced,—by the Editor, Mr. GEORGE DODD, author of "Days at the Factories," "British Manufactures," &c.



KNIGHTS' CYCLOPÆDIA

OF

the Industry of ALL NATIONS.

No. 1.

INTRODUCTION.

I. INDUSTRIAL EXHIBITIONS,

AT HOME AND ABROAD.

THE great Industrial Exhibition of 1851—great in every sense of the word, if worthily carried out,—will be a kind of summing up of the labours of half a century. It will be a practical test, whereby we may know how much, and of what kind, the first half of the nineteenth century has been able to achieve in the application of skilled labour. Before the present century, efforts were too scattered to be susceptible of easy comparison; and the great moving forces of industry, (so to speak) were yet in their infancy. In applying this designation to the *steam engine* and the *factory system*, we do that for which there is much warranty: each of these is a mighty agent both for *combination* and for *subdivision;* for applying to all work to be done, just so much force as will meet the requirements of the case; for economising space and time, capital and labour, materials and tools; for rendering invention and supervision doubly effective; and for developing an amount of precision and accuracy which never before marked industrial processes.

In the contributions, too, which science has made to manufactures, the present century stands out in bold contrast to those which preceded it. It was early in the century that Davy made those brilliant discoveries concerning metallic oxides, which have had so much influence in chemical manufactures. The labours of Dalton in respect to atomic laws of combination; Wollaston's researches into the nature of platinum; Davy's safety lamp, and the curious law on which its action depends; Liebig's remarkable labours; the wonders of electricity; the researches into the phenomena of waves and tides—these, and countless other instances, have had a more immediate practical bearing on manufactures, than was generally the case in respect to the scientific labours of former centuries.

It is not the object of the present paper to place the two years 1800 and 1850 before us, and to make them bear witness—each for itself, and each for the other—to the industrial progress which has been made in half a century; but we propose to trace the attempts which industry has made from time to time, to display its results by means of *exhibitions*. It was not until near the commencement of the present century, that men ventured to draw attention to manufactures as the materials for a public show. The glittering of tournaments, the panoply of war, the pomps of royalty, the ceremonies of the cathedral, the fictions of the drama, the fairs of the market-place—all were objects of public assemblages; but the time had not yet come when the artisan was to be the main exhibitor.

Such a time, however, did come at last; and it is creditable to our neighbours across the Channel, that they were the first to strike the key-note of this species of industrial concert—a concert which, national at first, may become inter-national ere long.

Mr. Digby Wyatt has afforded us the means for tracing the proceedings of the French, in respect to Industrial Exhibitions. The Society of Arts, which has within a recent period thrown into its proceedings a vigour analogous to that of its early days, deeming the Paris Exposition of 1849 a favourable occasion for collecting information, deputed Mr. Wyatt to visit that capital, with a view of enquiring into the origin, constitution, merits, and effects, of such enterprises. The result of his visit appeared in the form of a valuable Report, addressed to the President and Council of the Society; and this Report, in its convenient printed form, may safely be taken as an authority on the subject.

It was during the stormy period of the first French Revolution, when the bonds of society seemed to be snapped asunder, and when peril surrounded all the institutions of that country—it was at such a time that industry was first made the basis of a popular exhibition. At that period, and for many years previously, three manufactories in France had been under the especial rule and guidance of the government,—viz., the porcelain works of Sèvres, the tapestry works of the Gobelins, and the carpet works of the Savonnerie. In 1797 the French Directory appointed the Marquis d'Avèze, as commissioner for these national establishments. He found, on his appointment, that they were in a wretched condition: the operatives were reduced to great penury; and proofs were abundant that neither government care nor government funds had flowed in this direction, during the fearful tumults which had marked the infancy of the Republic. The Marquis conceived that he might give a new impetus to these three manufactures, by forming a public exhibition of the choicest specimens of their production. He memorialized the Minister of the Interior, and obtained his sanction; he applied for the use of the Chateau of St. Cloud, (which was then desolate and unfurnished), and obtained it. The floors were covered with superb carpets from the Savonnerie, the walls were hung with Gobelin tapestries, and the saloons and halls were adorned with the finest examples of Sèvres porcelain. A system was planned, whereby a fund might be raised by sales and by a kind of lottery, for the benefit of the workmen. But political vicissitudes cut short the project, and frustrated the object which the Marquis so praiseworthily had in view. A decree of the Directory was published, banishing all the nobility of France from Paris and its vicinity, and allowing only four-and-twenty hours in preparation for departure. The Marquis, as one of the nobles, was included in the proscription; and he had barely time, before the scant number of hours had passed, to place the treasures of St. Cloud under the care of other government authorities. Thus was the first French Industrial Exhibition strangled in its birth, after a few privileged persons had seen it, but before it had been thrown open to the Parisian public generally.

But the idea thus made public, was not lost. The spirit of nationality soon found inducements to further exertions. The Marquis returned from his proscription in the early part of 1798, and immediately made preparations for a second industrial collection. On this occasion he located it—not at St. Cloud—but in the Maison d'Orsay, in the Rue de Varennes. The Parisians here found collected, not only products from the three national establishments, but beautiful specimens of furniture, marqueterie, clocks, watches, bookbinding, silks, &c., contributed by the chief manufacturers.

These two preliminary Expositions may be considered the creation of one individual; but they were speedily followed by others which were more formally under government patronage. When Napoleon returned flushed with victory from his first Italian campaign, with visions of Roman triumphs in his mind, he bethought of a Temple of Industry as a worthy pendant to the Temple of Glory; and such a temple was erected in the Champ de Mars in 1798—with much frippery and tinsel —but with many solid advantages to manufacturers and their productions. The exhibition was open only three days, but the Parisians were nearly crazy with delight and self-laudation at the result. The Jury system (which we shall presently explain) was established; and among the nine jurymen we find the well-known names of Molard, Chaptal, Duquesnoy, and Berthard. We find, too, among the exhibitors and prize holders, the names of Breguet, Lenoir, Clouet, and Payen,—men of great celebrity in many departments of manufactures.

Such was the third French Industrial Exhibition, or the first strictly National, in which the charges were borne by the state. It is usually spoken of as the First Exposition. It was speedily succeeded by a second. The government determined to make them annual, and to admit provincial towns to an equality with Paris, in respect to specimens admitted; but this determination was not fully carried out, for the second exposition did not take place till 1801. The First Consul had by that time become the patron of science and of art, as of armies and navies; he visited—accompanied by Berthollet, Monge, and Chaptal—the manufactories of Paris, Rouen, Milan, Lyons, Brussels, Liège, and Aix la Chapelle, and encouraged the workmen by prizes and medals. It was under such auspices that the second National Exposition took place. It was held in the great quadrangle of the Louvre, which was fitted up with galleries for the purpose. As compared with its predecessor, this exposition was marked by the excellence of its woollens, cottons, carpets, fancy leathers, and printing; and it was made memorable by the first appearance, as an inventor, of the ingenious Jacquard. It is pleasant to bear in mind, at a time when English and French industrial products are about to be placed side by side in friendly competition, that Jacquard in part owed his eminence to the exertions of the English Society of Arts. This society, about the period now under consideration, offered a prize for the invention of a loom for weaving fishing-nets; and Jacquard produced a machine, consequent on this advertisement, which was the means of bringing him into favourable notice by Napoleon. The second exposition was open six days; it counted 229 exhibitors, against 110 in its predecessor; it was marked by the distribution of sixty medals; and its Jury contained the distinguished names of Berthollet, Berthoud, Guyton de Morveau, Prony, and Costaz.

The year 1802 witnessed the third National Exposition, held in the same place as the second. The days of exhibition were seven, the number of exhibitors was 540, to whom 254 medals, decorations, rewards, and "recognitions," were given. The period was marked by much extension of productive art—especially by the increased application of mechanical and chemical science to facilitate production, and the consequent reduction in price of all articles of popular demand. This exposition was the immediate cause of the establishment of the *Société d'Encouragement*, a kind of Society of Arts, which has rendered important service to French manufactures.

The fourth Exposition took place in 1806, under the blaze of the Empire, when the First Consul had become a King-maker. It was held in a fine building constructed on the *Esplanade des Invalides*, and lasted twenty-four days; there were 1422 exhibitors, among whom 610 honours were distributed. The great and distinguishing feature of this display were the variety and beauty of the textile goods. Printed cottons, silk and thread lace, blonde, cloth, imitations of Cachemere shawls—all these were conspicuous for their beauty in this exposition. Steel and iron manufactures, also, presented great marked improvements. It is remarked by Mr. Digby Wyatt, that "the isolation, which for so many years separated in so great a degree manufacturing France from the other producing powers of Europe,—while it placed her in many points of view in an unfavourable position,—yet by *forcing* her energies to supply *alone* what other kingdoms derived from mutual co-operation and dependance on each other, laid the foundation for that facility and universality of manufacture which so eminently distinguish her at the present day."

A long interval took place before France presented another exposition of industry. Napoleon was incessantly engaged in wars, and the drain on the national Exchequer for the support of his myriads of soldiers was continuous; and these circumstances probably tended to withdraw public attention from the more peaceful arts of production. And even after the restoration of the Bourbons—those who "forgot nothing and forgave nothing,"—four years elapsed before the industrial displays were resumed. At length, in 1819, the fifth Exposition was held in galleries constructed in the Court of the Louvre. It was open thirty-five days, and contained articles contributed by 1662 exhibitors, among whom were distributed no fewer than 809 medals and rewards of various kinds. Jacquard was again a prize-holder on this occasion; and the metal-workers, in steel, iron, bronze, plated goods, gold, and silver, exhibited a great advance in skill. The dyers and the calico-printers, too, came out in great force.

In 1823, after an interval of four years, the sixth Exposition occurred. Like its predecessor of 1819, it was held in the Louvre; but it had a longer existence, being kept open fifty days; there were 1642 exhibitors, and 1091 rewards given. Civil engineering displayed, at this exposition, more notable features than any preceding one.

The seventh Exposition was held in the Louvre in 1827, and exceeded all its predecessors in magnitude and duration; it lasted sixty-two days, had 1795 exhibitors, and 1254 prizes and honorary recognitions. The steam-engine and its wonders told more significantly in this exposition than in any former one, in the greater regularity of finish given to various manufactured articles, and in the greater cheapness and distribution of the products. Merinos had become an article of extensive manufacture; shawls, tulles, and blonds, were manufactured on a large scale: silks were, by the steam-engine, made to include products of the spun as well as the thrown material; mixed fabrics of silk and wool had come into use; cotton printing had become available for the gown of the peasant as well as for the dress of the peeress; and the making of paper in sheets of endless length had become one of the conquests made by steam-power.

Charles X. was expelled, and Louis Philippe elected to the monarchy, in the interval between the seventh and eighth Expositions; but these exciting events did not affect the general character of the Exposition of 1834. The site selected on this occasion was the *Place de la Concorde*, on the four sides of which were erected four pavilions. The exposition was open to public view during a period of sixty days; there were 2,447 exhibitors; and there were 1,785 rewards and recognitions distributed. M. Charles Dupin presided over the jury of this exposition, and it had the benefit of his long and intimate acquaintance with the resources and manufactures of France. Cylinder-printing of paper-hangings, the revival of the arts of enamel and niello, India-rubber goods, artificial ultramarine—these were among the novelties of the display.

The ninth Exposition, in 1839, far excelled all that preceded it, in magnitude, importance, and general excellence. The building constructed for it was in the great square (Carré de Marigny) of the *Champs Elysées;* and comprised a grand hall for the textile products of Mulhausen, a Gallery, and eight long apartments; it occupied an area of 120,000 square English feet, and cost 14,560*l.* The exposition lasted 60 days; the number of exhibitors was 3,281, and the prizes and honorary distinctions awarded were 2,305. Almost every department of French manufactures was represented on this occasion.

We shall presently speak of the Great French Expositions of 1844 and 1849; but there are a few illustrative details concerning the mode in which our neighbours manage these matters, which it will be interesting to notice here.

In the management of these Expositions, as brought into a regular system within the last few years, the Minister of Agriculture and Commerce, once in five years, commences the arrangements about twelve months before the stated period of exhibition. He communicates with the various chambers of commerce throughout France, to collect opinions and information that may be valuable. He presents a report and estimates to the legislature, by whom a grant is made sufficient to cover the whole expense of the undertaking. He appoints a central jury at Paris; and he empowers the prefects of departments to choose special juries. He controls every proceeding up to the time of the opening of the exposition: and he is responsible for the judicious expenditure of all the funds placed at his disposal. A considerable portion of the grants made for these French expositions is derived from fees paid on the granting of patents.

The office of the local special juries is a remarkable one, indicative of a thorough centralised mode of proceeding. The special jury for each district has to determine how far the goods forwarded to the chief town of the district may be worthy of admission to the exposition, and of transmission to Paris at the cost of the state; and it has to settle any minor local questions submitted to it by the central jury. In this we see one among many examples of the different spirit in which Englishmen and Frenchmen conduct their proceedings: in England our manufacturers would be very much inclined to rebel against a jury chosen—not by themselves—but by a magistrate, to pass judgment on their manufactured goods; while in France, these things are regarded as a mere matter of course. We must bear in mind, however, that in France the state voluntarily lends a fostering hand to art, science, manufactures, and literature; whereas in England all these are left to struggle into excellence as best they may. It seems to be agreed, moreover, that the persons selected to form the special juries are really fixed upon according to their fitness to judge on the matters submitted to them. The juries collect the manufactured goods in the chief town of the district, and make the necessary arrangements for forwarding them to Paris.

The central jury is a very important body, and always comprises names which France delights (and properly so) to honour. The number of jurymen has increased as the scope of the exhibition has become enlarged. In the first exposition the number was 9; and this number increased gradually to 27, 44, 53, and 64—the last being the number of the jury in 1849. Any one who is acquainted with the names of distinguished living Frenchmen, will recognise many such among the central jury of 1849—Arago, Blanqui, Chevallier, Chevreul, Didot, Dumas, Duperrier, Dupin, Durand, Ebelman, Laborde, Mathieú, Moll, Payen, Peligot, Pouillet, Seguier, &c. In the meetings of the jury, many important questions have to be decided. The hearing of appeals from the special juries,—the decision whether or not dealers shall be admitted to exhibit as if they were manufacturers; the consideration of the claim of dyers to a share of the honours accruing in respect to fine specimens of woven goods; the arrangements for setting models and machinery in motion; the exercise of a power of rejection, in respect to proposed exhibitors whose commercial reputation is not satisfactory,—such are among the matters which come before their notice in the preliminary arrangement.

It is a curious circumstance, and one that shows how little has yet been done towards a good classification of productive industry, that the juries have wavered considerably in their opinions as to the best arrangement of the specimens in the exposition and its catalogue. It is the same, in this respect, in France as in England: all is yet in a tentative state; systems are tried, to see whether they will work well, and then abandoned if not satisfactory, and others substituted. Costaz, Payen, Comte, Dupin, in France; Ure, Babbage, Barlow, Fergusson in England—all have proposed modes of classification of manufactures. In the exposition of 1806, M. Costaz adopted a topographical arrangement, according to the departments of France whence the specimens were sent. In 1819 he attempted to classify all arts into a sort of natural system ; but the separate headings amounted to thirty-nine, and were found to be confused and inconvenient. In 1827 M. Payen adopted a classification into five great divisions,—arranging the arts according as they are chemical, mechanical, physical, economical, or (that sad interloper in most classifications) miscellaneous, in their nature. In practice this was found defective, for two or even three of these characteristics often belong to the same manufacture. In 1834 M. Dupin proposed and adopted a classification which was found to work better than any which preceded it. He considered which among the many wants of man are supplied by any one particular branch of manufacture : he viewed man as a locomotive animal, a clothed animal, a domiciled animal &c., &c., and he traced this multiform animal through his various daily wants and employments. He thus arrived at a classification, in which all arts are placed under nine headings, according as they contribute to the alimentary, sanitary, vestiary, domiciliary, locomotive, sensitive, intellectual, preparative, or social tendencies of man. In 1839 the same system was adopted. In 1844 and 1849 attempts were made towards an eclectic combination of two or three of the above systems ; but it does not appear—so far as the materials are offered for forming a judgment—that these systems presented any marked advantages.

In France the awarding of medals, decorations, and similar encouragements, is carried to a much greater extent than in England, and is looked up to as matter of great importance. *We* have the art of awarding medals twenty or thirty years after they have been earned, and when the veteran recipients are fast dropping into the grave. The medals of the French expositions have in some years exceeded three hundred in number—gold, silver, and bronze. These have indicated three gradations of merit ; and two other gradations are indicated by "honourable mention," and "favourable notice." In some cases the jury awards prizes to persons who have rendered service to the industrial arts of a kind not susceptible of being represented by productions exhibited in their name.

Our own country must now claim a little attention.

It is difficult to say when and where our first exhibitions of industry took place ; for they have hitherto been, for the most part, combined with exhibitions of fine arts and of curiosities, knick-knacks and trinkets, marvels and oddities. Perhaps the *Museum of the Society of Arts* is best worthy of being placed at the head of the list—that dusty and old-fashioned looking museum, which so many persons have visited for so many years. We speak not so much of its present, as of its past condition ; for what with "mediæval exhibitions" at one time, and "modern exhibitions" at another, this old museum has been somewhat thrown into the shade lately. Those, however, who remember it in its old form, know that it contained much which instructively illustrated the progress of manufactures. There were specimens of Leghorn plait, in juxta-position with those improved British specimens which the Society has done so much to encourage. There were specimens of hemp and flax, designed to show how far England could grow these important materials of manufacture. There were samples of Assam tea, and Assam silk, of English silk, of English wool, of goats' hair ; all designed to test the capability of Britain and her colonies in such productions. There were bits of machine-lace placed by the side of other specimens of pillow-lace. There were examples of the contributions which art may be said sometimes to make to the cause of humanity—such as fire-escapes, chimney-sweeping apparatus, teaching apparatus for the deaf and the blind, magnetic mouth-pieces for needle-grinders, &c. There were models of the safety-lamp, and of various other useful contrivances; there was, too, a somewhat extensive collection of pigments, oils, varnishes, cements, and other substances used in the arts; for this useful society does not confine its operations to the encouragement of any art or manufacture in particular, but to the advancement of productive industry generally—whether in the raw material to which manufacturing art is afterwards to be applied, or to the implements or processes by which this manufacture is conducted.

We hardly know how to bring in the *East India Company's Museum* into our list; yet there are a few curiosities of manufacture in that most miscellaneous assemblage. On one side are exhibited models of Asiatic ship-building, such as the Chinese junk and the Sumatran proa; on another are Burmese musical instruments; here we have models of Hindoo looms, ploughs, mills, bellows, coaches, windlasses, pestles and mortars; there we see a collection of sabres, daggers, hunting-knives, pipes, and bowls. Specimens of dress from the Eastern Archipelago; painted tiles; beads and glass trinkets; models of Chinese villas, in ivory and mother-of-pearl; Chinese lanterns, of horn and other materials; Chinese writing, drawing, engraving, printing, and counting-machines; palanquins and howdahs—all such are instructive, in respect to the insight they give concerning the arts in the East.

The *Asiatic Society's Museum* is very similar to the one just noticed, in so far as regards the oriental nature of the contents. Here weapons of offence and defence are very numerous—spears, lances, javelins, darts, bows, arrows, swords, daggers, knives, axes, rifles, muskets, pistols, firelocks, shields, and fighting-dresses. Among other varied objects (which we only notice so far as they illustrate manufacturing art) are vases and vessels of oriental workmanship; Hindoo astronomical and musical instruments; a highly curious collection of japanned wicker baskets, with specimens of the japan and varnish employed in their manufacture; models of Hindoo agricultural machines; models of pagodas and temples, and of the car of Juggernaut; and a miscellaneous collection of articles of Chinese furniture and personal decoration.

The *United Service Museum* has its few specimens of manufacturing skill, mostly in connection with the arts of war, and mostly brought by military and naval officers from foreign countries. Models of shipping and naval apparatus; specimens of life-buoys and safety garments; models of gun-carriages; a model of a bridge of boats: a portable Russian camp-kitchen; military dresses and accoutrements; grenades and shells—these illustrate more or less the ingenuities of manufacture.

Of a different nature is the *Museum of Economic Geology*, in so far as it exhibits the *materials* rather than the *results* of manufacture. Everything that can illustrate the mineral riches of our country is here instructively displayed. There are models of mines, and of the machinery employed in working them; there are specimens of ore, and the various stages of its preparation; there are sections of strata, and of wells sunk through them; there are specimens of coal, of clay, of sand, and of the various materials on which skilled labour is afterwards to be employed —in short there are to be found within these walls the beginnings of the industrial alphabet: the first link of the manufacturing chain.

If we view it aright, the *British Museum* is an exhibition of manufactures, as well as of art, science, and literature. Let us take our stand for a time in the "Ethnographical Room," and look around. This is one of the most instructive rooms in the museum: it contains specimens illustrative of the manners, customs, arts, and implements of various nations. The Chinese, the Hindoos, the Japanese, the Africans, the North American Indians, the Peruvians, the Mexicans, the Guianians, the Chilians, the Yacatans, the Esquimaux, the Australasians, the Polynesians,—all are represented; and these representations do not relate merely to those nations, but were *made by them*, so as to be indices of their manufacturing skill. Dresses, ornaments, furniture, weapons, vehicles, buildings, instruments, vessels, toys, books—all are here to be met with, and all are full of instruction to one who brings an observant mind in aid of an observant eye.

All the above six examples (and there are many others in London and the country) are museums belonging to the nation or to public bodies, and are open gratuitously. There is another class of exhibitions, in which the primary object is a pecuniary one—the shilling, which every visitor pays for admission. Of course the fostering of national manufactures cannot be looked for under such circumstances; yet there have been many interesting collections displayed under such auspices. We will briefly advert to a few of them.

Many into whose hands this sheet may fall will perhaps remember an exhibition which was opened some twenty years ago, at or near the spot on which the National Gallery now stands. It was a collection of manufactures, ornaments, machines, and curiosities, of a somewhat attractive nature; and was, we believe, set on foot by the same society which afterwards instituted the *Adelaide Gallery of Practical Science*. This gallery has changed its flag: it has given up science and manufactures, and has succumbed to casinos and sherry-cobler. Yet we remember when it was a really instructive exhibition. Besides the marvels of the steam-gun, and of the combustion of steel, and the broiling of a beef-steak by a convex lens, there were many arrangements of specimens which tended to illustrate the processes of manufacture. Specimens of geological strata were grouped in one place; specimens of woods used in the arts, in another; while there were many groups, each of which contained a series illustrative of the successive stages through which a manufactured article passes—such as a knife, a fork, a file, a flask, a button, a candlestick, a tea-pot, a needle, a pin, hooks and eyes, combs, hats, glass, earthenware, silk goods, cotton goods, woollen goods, caoutchouc goods, &c. In all these cases we had the rough, the partly finished, and the highly finished articles displayed for us, in such a way that we could trace its manufacturing history in an intelligible series. These epochs in the history of a knife were eight or ten, in that of a fork still more, in that of a needle no fewer than nineteen.

Although the institution just named has slipped out of existence, its younger sister, the *Polytechnic Institution*, still survives, and seems to gain strength as it grows older. Its music, its lectures, its dissolving views, its semi-science, we have not here to do with; but its illustrations of manufactures have the same kind of interest as those which have just passed under our notice. In the "Hall of Manufactures," just within the entrance; on the floor and in the galleries of the great saloon; and in some of the rooms at the two ends of the building—are various specimens, which illustrate either the materials of manufactures, the finished articles themselves, machines for aiding in manufactures, or moving powers for setting the machines in motion.

Why should we not class Mr. Catlin's most unique *Indian Collection* among the exhibitions of industry? Did it not illustrate the ingenuity and manufactures of a remarkable people, as well as their features and their habits of life? Though the pictures were the main object of the collection, they were not the only memorials of the Red Man. There were some of the real products of Indian manufacture. Among them was a wigwam or lodge of the Crow Indians, twenty-five feet in height, and capable of sheltering eighty persons: it was brought all the way from the Rocky Mountains. Then there were Indian cradles, lances, calumets, or "pipes of peace," tomahawks, scalping knives, bows, quivers, spears, shields, mens' and womens' dresses, necklaces, mocassins, belts, pouches, war clubs, robes, mantles, wampums, whistles, rattles, drums, &c.—all of which displayed the mechanical art, such as it is, of these children of the prairies.

The *Chinese Collection*—was not this, too, an exposition of manufactures? Did we not here find an admirable series of illustrations of the art, the invention, the ingenuity, the mechanical contrivances of that remarkable people? When this singular ship's cargo was brought to England in 1842, and when a capacious and well-planned building was constructed for its reception, the Londoners and the visitors to London flocked in thousands to witness the display; and we believe the general tendency of the spectacle was to raise the character of the Chinese in the estimation of those who had before known so little of them. How wonderfully exact were the models of all the manufacturing processes! How life-like were many of the scenes, representing mechanics in their accustomed dresses, pursuing their accustomed avocations, with their accustomed tools, on the accustomed material! The ivory carvings, the inlayings, the turned work, the japan-work, the basket-work, the jewellery, the cutlery, the silks, the cottons, the nankeens, the shoes, the hats, the tools, the implements and instruments, the weapons—all were there, and all gave a most interesting insight into the industrial genius of that remarkable people.

There have been many other exhibitions in this country (and we may suppose in other countries likewise), in which manufacturing skill has been one of the points of attraction, for which visitors are expected to be willing to pay. But we must hasten to the remarkable Expositions of the last ten years: these we shall notice in chronological order, including many both at home and abroad.

One of the first attempts to establish a temporary exhibition in the provinces, in which specimens of manufactures were to fill a place in the programme offered to visitors, took place at *Manchester* in 1839. It was held in the Mechanics' Institution, for whose benefit, as a commercial transaction, it was set on foot. The gentry and the manufacturers lent, for the occasion, whatever they thought might be of striking interest—whether in pictures or other works of art, in machinery and manufactures, or in miscellaneous curiosities. The visitors were numerous, the funds raised considerable, the satisfaction general; and a hint furnished which future years and other towns have not failed to use profitably. It is true that manufactures bore anything than a lion's share in the assemblage; still there was enough to serve as a beginning: Mechanical Industry took its place by the side of Fine Art; and the two have year by year been drawn into closer and closer communion—new ties bind them, as each becomes more and more developed.

Leeds, the metropolis of woollens, did not lose sight of the example furnished by the metropolis of cotton. She, too, had a Mechanics' Institution; and this institution was located in a building so poor and so comfortless, that the thought of imitating Manchester arose—the thought of raising funds towards the payment for a new structure, by an exhibition of mingled art and manufactures. Let us not think lightly of such an attempt because money was one of its motives: the money was to be the return for money's worth, intellectually and otherwise, and was to be worthily applied towards an educational and intellectual object. Would that all exhibitions could claim such a character! The committee invited loans of such objects as might be fitting for such an exhibition; and the invitation was liberally responded to. The pictures were very numerous, but the machinery was also varied and interesting, and the result was that a considerable sum was realised for the object primarily held in view.

Liverpool, and other towns in the north, followed the example of Manchester and Leeds; indeed, wherever a Mechanics' Institution has existed, there has been an incentive to such exhibitions, not met with where no such nucleus of association exists.

The order of events now again takes us across the channel. The tenth great *French Exposition*, in 1844, was, like its predecessors, exclusively French,—it was a display of the industry of that nation; and no one could glance around at the tasteful and varied products exhibited—at the countless forms which metal and wood, glass and porcelain, fibre and sap, colours and chemicals, were made to assume—without feeling that such a nation must perforce occupy a lofty position among the industrial workers of Europe.

The arrangements for this display were on a grand scale—a scale which the French know how to adopt in most of their public "demonstrations," whether warlike or peaceful. A plot of ground was appropriated to this purpose in the *Champs Elysées*, the Hyde Park of Paris. This ground comprised an area of more than twenty thousand square yards, almost every inch of which was crowded with the fruits of French industry and taste. Each front of the quadrangular building presented a low, long, architectural composition, simple enough in its way—pierced by pedimented windows, and having a hexastyle portico in the centre. Two or three of the competition drawings for the Hyde Park structure, sent in before the Commissioners had determined on the adoption of Mr. Paxton's plan, and exhibited at the rooms of the Institute of Civil Engineers, bore considerable resemblance to the Paris structure of 1844. The grand entrance was on the north, with a "Royal saloon" on the right, and a "Jury's saloon" on the left, of the portico; at the centre of the south side was a private entrance, with rooms for the Directors of the Exposition; while at the centre of the east and west sides were gates for departure. A palisade girded the whole building, at a distance of several yards from the walls; and within this palisade were a guard house, a depôt for the fire-brigade, and clusters of the coarser varieties of agricultural implements.

Such were the external arrangements of the building, which, in May 1844, was thrown open to the gaze of the admiring Parisians. The hours for the general public were between twelve and four o'clock each day; but private admission was obtainable at an earlier hour by means of tickets; and it indicated considerable liberality of feeling, that any stranger who presented his passport at the gate was admitted to the private view without further introduction. The contents of the building were displayed in forty galleries or ranges of stalls, the avenues between which had an aggregate length of more than five miles. In the centre of the whole was a colossal statue of St. Louis, which served as a sort of guide in traversing the numerous avenues. With a few exceptions here and there, a pretty general system of classification was followed out—the larger machinery and metal work being in the centre, the textile fabrics mostly on the south side, the household furniture for the most part on the north side, and the almost endless variety of ornamental manufactures on the east and west. By far the greater number of the galleries ran in ranges from east to west, but those at the ends extended north and south. A visitor looking round him from the central statue, saw lengthened avenues of metal goods of all grades and uses,—steam-engines, fire-engines, spinning machinery, throwing machinery, cutting and punching engines, mechanical inventions, stoves and smiths' work, locks and keys, iron bedsteads, printing presses, jacquard machinery, zinc work, &c. In other places the more fanciful and artistic applications of metal met his view—philosophical and mathematical instruments, balances, guns and pistols, swords and bayonets, bronzes, clocks and watches, lamps, cutlery, jewellery, daguerrotype plates. The products in which earths, minerals, or glass bore a chief part, were represented by mirrors, cut glass, porcelain, earthenware, marble and alabaster work, stuccoes, statuary, &c. The textile or woven collection was most diversified—as any one might expect, who knows how much attention is paid in France to fancy articles in this department: here were woollen cloths, carpets, draperies for hangings, mixed fabrics of cotton and wool, calicoes; there were silks, merinos, muslins, velvets; and at other places damasks, shawls, embroidered goods, prints, handkerchiefs, mousseline-de-laines, tapestry, cachmeres, &c. It was a remarkable feature in this section of the exhibition that cotton goods—the plain, every day, serviceable cotton goods—bore but a very humble share in the display: silk and wool greatly predominated over cotton. There is a deeper reason than mere choice in this circumstance: it is typical of the relative importance in France, of different departments of textile manufacture—in England the strength, commercial if not artistic, lies in another direction. There was not wanting, too, for those whose curiosity led them to seek further specimens of dress, food to satisfy the search: there were felted goods and hair-plaited goods, straw bonnets, feathers, artificial flowers, &c. Chemical ingenuity presented its perfumery, its soaps and candles, and its comestibles. The workers in wood supplied their pianos, organs, billiard tables, cabinets, household furniture generally, and specimens of inlaying; while the printers, the bookbinders, the paper-makers, the umbrella-makers, the saddlers, the coachmakers—all put forth their claims to a meed of approbation. The exposition was open sixty days; there were 3281 exhibitors, of whom 2305 received honorary notices of one form or other.

The late King Louis Philippe, whose eventful life has so recently terminated, took a most active part in the planning of this exposition. It will be a graceful feature in the history of the past, when the chequered events of his career become recorded, that—while often engaged in the turmoils of political strife—he yet urged his countrymen to achieve the peaceful victories of industry. And when the exposition was opened, the King spent several hours a day, on many of the days (Mondays) when it was not open to the public, in a minute examination of the contents, with a view of ascertaining, by the evidence of his own eyes, what his subjects could or could not effect by the force of their own manipulative talent. It is recorded, too, that the chief manufacturers were recognized by the monarch as benefactors, as the nobles of industry, and were treated by him accordingly:—

"The King can mak' a belted knight,
A marquis, duke, and a' that,
But ————"

We need not follow out Burns's thought: a king cannot make a manufacturing people; but he can give them kindly countenance in their efforts to make themselves such. And what is graceful in a King, can hardly be otherwise in a Prince Consort.

It was in May of the next following year, 1845, that the great "*Free Trade Bazaar*" was held in Covent Garden Theatre; a bazaar which had a bustling and exciting existence of about twelve days. Pity it was, perhaps, that such a creditable and honourable display should be indissolubly connected with a great political movement, which drove men into two antagonistic parties, and gave a party-colouring to an industrial developement. But whatever may be said of *national* exhibitions, it can hardly be doubted that those of an *inter-national* character—such as that which is looked forward to by all the world in 1851—are essentially dependent on liberal commercial principles for their due carrying out, nay, for their very origin; and even if this position were disputed, the industrial results of the bazaar may be studied without reference to any disputed commercial doctrines.

What, then, were the aspects which the bazaar of 1845 presented? Manufacturers in various parts of the country, favourable to those commercial views which were entertained by the managers, sent up to this Bazaar the choicest productions of their skill. The theatre was skilfully arranged for this occasion. The stage, orchestra, and pit were all floored over to make one large hall, while the boxes and walls presented a vertical surface for a gorgeous display of the products of industry. The centre of the vast area was so fitted up with ranges of stalls, as to leave convenient avenues between the stalls and the sides of the building; and the stream of visitors was so judiciously directed, that by following a certain route every stall and stand came successively under the notice of the eye. The visitors were admitted by the room which was then known as the Shakspere gallery, but which Mr. Albano has probably since demolished in his transformation of a temple of Shakspere into a temple of Apollo. From thence the body of the house was entered at the back of the pit; and the moving multitude passed round the north, west, and south sides in succession—emerging at the back of the pit, but by a different door from that which furnished admittance. The extreme western end was occupied as a refreshment room; but all the rest of the area was appropriated to specimens of manufacture. The arrangement of these specimens was striking and interesting; for each manufacturing town had its own stall or group of stalls. Every stall had inscribed over or within it, in characters which were made to bear part in the general decorations, the name of the town to whose industrial products it was set apart. Thus each town told its own tale: each made its appeal to the spectators in a mode more forcible than mere words could do. The social history of each body of artisans was written in the display of goods exhibited in the stalls of the towns to which they belonged. A sort of industrial map of Britain was presented by the whole assemblage, in which the skill and labour and capital of each town's population were indicated, much as a geological map exhibits the relative distribution of mineral wealth beneath the soil.

Nor were the great manufacturing towns of the north the only foci of industry, whose names were inscribed on these walls. If Lancashire had representatives from Manchester, Bolton, Rochdale, Bury, Blackburn, Ashton, Staleybridge, Liverpool, Lancaster and Preston; if Yorkshire were represented by Leeds, Halifax, Bradford, Huddersfield, York, Hull, Barnsley, Wakefield, and Sheffield; if Cheshire sent its delegates from Warrington and Stockport; so did other parts of the north send their industrial products from Carlisle, Newcastle, Stockton, &c.; Scotland, from Edinburgh, Glasgow, Dundee, Paisley, and the far distant Shetlands; the Midland Counties, from the Potteries, Northampton, Dunstable, Luton, Dudley, Birmingham, Wolverhampton, Kidderminster, Leicester, Coventry, Derby, Nottingham, Norwich; the west from Swansea, Exeter, Bristol, Coalbrookdale; while a sprinkling of towns in the east and south found a few hives for their working bees. The display of beautiful forms and colours was almost as unquestionable as the excellence of the handy work: we say "almost"—for it is well to leave a loophole for any improvements, in the aesthetic relations of manufacturing art, which our continental neighbours may suggest to us next year. The much disputed point of the inferiority of English taste to French taste, and the amount of difference if difference there be, will never be decided except by a more extended and a more direct comparison than has yet been presented in any one collection. Our manufacturers know the length and breadth of the field in which they have to contend: they know in which departments of industry they have the reputation of taking the lead before all the world, and in which they are supposed to lag somewhat behind; and the time has arrived for them to prepare for the battle, armed with the best of all weapons—perseverance, supported by science, adorned by art, and quickened by invention.

Every one who has a moderate acquaintance with the localization of manufactures in this country, will form a judgment of the kind of products exhibited in each department of the bazaar. How every combination of cotton fibres which ingenuity can devise, were exhibited in the Lanacashire sections; how the West Riding gloried in its broad cloths from Leeds and Halifax, its merinoes from Bradford, its many-coloured fancy cloths from Huddersfield, its linens and damasks from Barnsley, its cutlery from Sheffield; how Nottingham produced its bobbin-net and its cotton hosiery, Leicester its worsted hosiery and its warm lambs' wool garments for winter, Derby its silk hosiery, Coventry its ribbons, and Norwich its shawls and bombazeens; how North Staffordshire was represented by its exquisite porcelain, and South Staffordshire by its countless varieties of useful articles in iron and steel, Birmingham by its products in almost every metal that has yet been brought within the range of manufacturing art—all this needs scarcely be told. Besides the ordinary products of the workshop and the factory, there were specimens highly interesting for the novelty which they presented. There was a roll of tissue paper a mile in length, made from the fibres of worn-out coal-pit ropes; a tapestry copy of one of Landseer's pictures, containing three quarters of a million of stitches; bobbin-net for ladies' dresses, with a printed pattern impressed on it; horsehair covers for chairs, damasked both in pattern and in colour; copies of the "Queen's Apron," made from the wool of an Alpaca belonging to her Majesty; muslin printed in gold by the electro-metallurgic process, &c.

The same year, 1845, calls our attention to another part of Europe—one of the German states. *Bavaria* has been the first country to provide a *permanent* building for the holding of Industrial Exhibitions. It was fitting that a monarch who had adorned Munich with such choice works of art, who had built such structures as the Glyptothek and Pinakothek as depositories for sculptures and pictures, who had fostered the genius of Von Klenze in architecture, Schwanthaler in sculpture, Kaulbach in encaustics, Cornelius and Schnorr in frescoes—it was fitting that such a sovereign should hold out a hand of encouragement to industrial art, which presents so much to, and receives so much from, art in its higher acceptation. Ludwig of Bavaria will be remembered for all this, when his foibles are forgotten. It was in 1845 that the building above alluded to was finished; and the site chosen for it was near the Glyptothek—a neighbourhood of good augury. The sides of the building are relieved from absolute plainness by ranges of pilasters, supported by a rusticated basement, and supporting a cornice; but the spaces between the pilasters are plain wall, without windows. In the centre of the principal front, towards the Konigsplatz or King's Square, is a portico of fine proportions—octastyle, Corinthian, and elevated on a lofty flight of steps. The pediment contains sculptures from models by Schwanthaler. In the centre is an emblematic figure of Bavaria enthroned, and surrounded by figures representing sculpture, architecture, painting, encaustic printing, glass painting, metal casting, coining and medalling. The extremities and summit of the pediment exhibit two sculptured lions and a phœnix. The interior of the building contains a vestibule and seven large apartments, lighted from the top; besides which there are two rooms and two corridors lighted by windows. Below the main suite of rooms are warerooms for unpacking the articles sent for exhibition, and apartments for the officers of the establishment. The area of flooring in the exhibition rooms is somewhat under 2,000 square yards—consequently less than one-tenth of that presented by the Paris structure of 1844; the flooring is of oak, diversified into pattern by parquetry. The walls are tastefully painted, in subdued colours; the ceiling is coffered, and so provided with skylights as to diffuse an equable light over the rooms; and the roof is covered with metal. The building is fitted for the reception either of works of art or of manufactures. The first exhibition was of the former kind: comprising pictures, drawings, lithographs, statues, busts, medals, stained glass, &c.

Manchester presented its "Exposition of Industrial Art" in 1846, under the auspices of the Directors of the School of Design in that town, and within the walls of the Manchester Athenæum. The Free Trade Bazaar, at Covent Garden Theatre, had had one unfavourable feature attached to it: in so far as it was a bazaar, anything and everything was saleable, if purchasers presented themselves. Consequently many of the stalls were emptied of their contents within a day or two after the opening of the assemblage. The manufacturers were not by any means dissatisfied with such a result; while the lady stall-keepers were anxious to present as favourable a cash-balance as possible, in respect to the object for which they had become amateur tradeswomen. It did not follow that this circumstance should necessarily and directly vitiate the advantages likely to result from a grouping together of the industry of all England; because there was a general desire to produce the *best* in each class; but still it had a tendency to induce the depositors to send a large per centage of trinkets and mere ornaments, instead of productions of a more permanent and solid character. The French have always been averse, in their expositions of industry, to anything which may approach the bazaar system; and it is evident that the real influence of example, of honourable rivalry, in the production of excellence, ought at such places to be kept free from any immediate alloy of bartering and commercial transactions. It is to give producers an opportunity of learning from and profiting by each other, and to the rest of the world an opportunity of seeing what industrial art has in store for them, that the exhibitions are valuable—the buying and selling are to be the fruits of after growth.

At Manchester the specimens exhibited bore immediate relation to the manufactures of Lancashire, rather than to the manufacturing counties generally; but still there was a very varied and beautiful collection; and the exhibitors strove earnestly to show that a high order of decorative art is now exhibited by the manufacturers, aided in part by the instructions which pattern-draughtsmen receive from the several Schools of Design. Being under the management of the directors of the Manchester School of Design, this exhibition was made a means of showing the progress of the pupils: many specimens produced by the pupils being placed around the walls of the exhibition rooms. Prizes were given, not only for the best designs, but also for the best fabrics to which new designs had been transferred. Amongst the productions for which prizes were awarded were a six-coloured mousseline-de-laine, calico-prints in a single colour each, furniture prints or chintzes, models of flowers and natural objects, designs for a single-colour printed muslin, &c. The miscellaneous articles comprised carpets of singular beauty; porcelain and pottery of every class—from the costliest table-services to the humble but neatly formed vessel of earthenware; papier-maché furniture and ornaments; wood-carvings, produced both by hand and by machine; furniture and cabinet work; Spitalfields and other silk goods; bronze and iron castings; glass manufactures; Paisley shawls; wool-mosaics; cabinets and other articles in embossed leather; paper-hangings; caoutchouc manufactures, &c. One of the specimens exhibited had that kind of interest which attaches to all attempts to introduce a new manufacture, a new material, or a domestication in England of a culture usually belonging to other countries. The specimen in question was a rich brocade, made from silk reared in England. That silk-worms *can* be fostered and reared in England, is well known to thousands who have derived an innocent and instructive amusement from the pursuit; and that attempts have been made time after time, to introduce the culture as a commercial enterprise, is equally known to that smaller number of persons who have attended to the history of manufactures. The piece of brocade exhibited was a counterpart to another piece presented to and accepted by the Queen: it was presented by Mrs. Whitby, a lady who had reared the delicate creatures which produced the silk. This lady, with a motive and a perseverance which deserve all praise, devoted eight or ten years to a continuous study of the subject; she imported into England above a thousand mulberry trees from North Italy; she planted them in the grounds of her estate near Lymington; she fed and tended the silk-worms upon the Italian plan; she purchased winding-reels, heating apparatus, and other appliances necessary for the work; and she finally produced silk which was pronounced by competent authorities worthy of being woven into costly tissues. This is not the place to discuss the reasons why such enterprises have never yet been commercially successful in England, owing to rate of wages, uncertainty of climate, and other circumstances; but it *is* the place in which to join in an expression of thanks to a lady who so laudably makes experiments on the actual capabilities of the system.

It was understood, at the time of the Manchester Exposition, that many of the manufacturers were deterred from sending specimens of their choicest patterns, by dishonesty on one side and defective law on the other. A sad blot this! The small calico-printers (small in morals as in capital) have been wont, too many of them, to avail themselves of patterns which have been provided and paid for by the owners of larger establishments. And this—not when the pattern has had its day, and remunerated its inventor—but immediately on its publication; and being free from artistic charges, they have been able to undersell the real owners of the pattern. The wholesale dealers, who are the immediate purchasers from the manufacturer, notified in some cases their determination not to purchase goods, the new patterns of which had been publicly exhibited: on the ground that the patterns might be copied by other printers, and sold to other dealers at lower prices. It would not be difficult to show that—even in respect to these minor manufacturers—"Honesty is the best policy." The bearings of legal protection on artistic and mechanical inventions are more fruitful in results than many readers suppose.

Belgium came forward in 1847, with her "*Exposition de l'Industrie Belge.*" Brussels became in July of that year, a centre of attraction to those who wished to witness the progress of manufacturing art in that country; it was the third exhibition of the kind since Belgium became politically severed from Holland; and it received all the *éclat* which the presence of royalty and of official dignitaries could give. None of the ordinary buildings of Brussels being large enough for the occasion, the specimens were exhibited in the *Nouvel Entrepôt* on the quay, a large square edifice connected with commercial matters. The building is placed in close vicinage to the navigation system and the railway system of Belgium, and has thus admirable facilities for the transport and admission of manufactured products. The Entrepôt in its ordinary commercial arrangement, has an open court in the centre; but on that occasion the court was covered in, to form a large middle hall, while the surrounding building was laid out in galleries. Every available yard of space was occupied. Upwards of one thousand persons or manufacturing firms sent specimens for exhibition.

Some of the towns of Belgium have been so long celebrated for the exquisite specimens of workmanship which the lace-makers are able to produce, that a display of such articles was naturally to be expected at the Brussels exhibition. It was stated that on that occasion Brussels lace was exhibited, made of thread so exquisitely fine, that one pound weight of it was worth 3,500 francs—140*l.* sterling. Linen thread worth three times its weight in pure gold! This is indeed a striking exemplification of the manner in which labour imparts value to raw material. The lace, the damasked linens, the diapers, the table-cloths, these were among the choicest productions exhibited. As to the Brussels point-lace veils and robes, they are so enormously costly, that none but the wealthy can purchase them. On the occasion in question, an exquisite handkerchief, covered with the richest design, was exhibited, made of the costly thread just alluded to: a thread so gossamer-like, that a single filament was scarcely visible, even when backed by a blue ground. One specimen was a handkerchief worked for the Queen of Spain, and valued at 5000 francs or 200*l.*! Here pure gold sinks fairly beneath notice, as a standard of comparison; we might almost venture to say that such an application of linen thread is worth its weight in diamonds. Belgium is rich in various kinds of pottery and porcelain; but in artistic taste she scarcely comes up to her neighbour, France, whose designs are rather servilely copied. Liége is skilled in metallic manufactures, many of which adorned the exhibition. Among articles in glass were tables, an inch in thickness, exquisitely veined or streaked in colours; they pointed out one of the many novel applications for which this beautiful material is adapted.

As, in England, the glass duties of past years tended to repress invention and enterprise in that most attractive branch of manufacture; as our window duties interfere both with our freedom of ventilation and with the architecture of our private houses; as our soap duties offer a kind of premium for unwashed faces and unwashed garments; as our Insurance duties are a direct discouragement to prudence and forethought—so in Belgium certain fiscal arrangements play sad havoc with the free encouragement of manufactures. An annual tax is laid on all household furniture, in the form of a per centage on the assessed value. The consequence is, that the Belgian nobleman spends his fortune rather on pictures and other untaxed luxuries, than on furniture. This is all well for the pictures, and for those who paint them: it is all well for those who are employed in the productions which escape the impost; but it presses hard on those whose time, talent, and capital are expended on the production of the ordinary kinds of household furniture. Most of the Belgian houses are thus under-furnished: their domestic accommodations do not correspond with the wealth of the owner: there is baldness, bareness, cheapness, where else there might be a fair exercise for the display of the ever-varied products of industry in these departments of manufacture. Inventors, mechanicians, artists, philosophers—all may combine to aid the progress of manufacturers; but unless governments float with the stream, there will ever be a hindrance of one kind or other.

In the management of the Brussels exhibition, encouragement was sought to be given to ingenuity and talent, by awarding prizes to the most deserving exhibitors. The delicate task of awarding these prizes was entrusted to a jury, formed of a number of scientific persons deputed by the government; they were to examine all the articles displayed, and report on their merits; the government gave the prizes in accordance with the report; and a copy of the report was ordered to be presented to the minister and consul of every foreign power. The exhibition days were thus arranged—on Sundays, Wednesdays and Fridays, free admission was granted between the hours of ten and three; on Mondays, Thursdays and Saturdays, between the same hours, the admission was by tickets, for which half a franc each was charged; on Tuesdays the exhibition was open only for the Commissioners and privileged persons. All the half-francs thus taken were distributed to the hospitals of the Ursulines and St. Gertrude. In those cases where manufacturers had been put to greater expense than usual in preparing specimens for exhibition, the commission contrived a sort of Art Union lottery for their benefit; tickets were sold at ten francs each, to any who chose to embark in the lottery; and with the produce of those tickets, specimens were purchased by a managing committee—such works being selected as were costly, rather for the labour bestowed upon them than for the value of the material.

We turn from *Belgium* to *France*. That France should have been able to produce such an Exposition as that of 1849, after such a year of tumult as 1848, speaks much for her elasticity. Whether for fighting or dancing, for barricading or manufacturing, her children throw a wonderful amount of energy into their proceedings, and untiring ingenuity in finding out means for setting their plans in operation.

The building for the Exposition of 1849 occupied the same site as that for 1844, between the great avenue of the Champs Elysées and the river Sêine; but it was very much larger. It was about 675 feet long, by 328 wide, exclusive of the space for the agricultural department, and covered an area of 240,000 square feet—about one-third the area of the building in Hyde Park. Around the four sides of the building extended a gallery about 90 feet wide, divided into two avenues by a double range of pilasters; the whole width of gallery was so arranged, that there were four passages for visitors, two rows of manufactured goods on stalls, two rows placed against walls, and one row between and around the pilasters. The interior area of the great quadrangle was crossed by two transverse galleries, which thus left three courts; one court contained a beautiful fountain and a horticultural collection; another had an immense reservoir; and the third contained specimens of large metal-work. In addition to the main building was a shed of large dimensions, about 300 feet long by 100 in width, appropriated to the reception of agricultural implements and live stock—for it was one feature of this Exposition, as compared with its predecessors, that the skill of the grazier was represented as well as that of the manufacturer. The entire range of buildings was constructed of wood, and roofed with zinc; the cost was about 16,000*l.*—the materials becoming the property of the contractors after the termination of the Exposition. The number of Exhibitors was 4,494. The display was open to the Parisians for a period of fifty-six days; and the admission was gratuitous on Mondays, Wednesdays, Fridays, and Saturdays, between the hours of eleven and five; on Thursdays the admission was charged one franc, towards a fund for the aid of the poor; and Mondays were appropriated to the Jury who were, at their leisure, to award the prizes for the various articles exhibited. At hours before and after the public exhibition, on all the days, admission was given by tickets, to learned foreigners, distinguished personages, representatives of the public press, &c.

In glancing over the plan of the building, and the arrangement of the manufactures, as given in Mr. Wyatt's Report, the eye fails to catch any very marked system of classification, although two systems have evidently been attempted—the *topographical* and the *material*. Thus, on the west side we see "Parisian" goods; while on various parts of the north and south sides are named the departments and towns of Gard, Rhône, Lyons, Roubaix, Elbœuf, Haut-Rhin, Rouen, Sedan, Troyes, Orne, Nord, Turcoing, and Rheims. But the classification according to the materials of manufacture is somewhat more distinctly marked, though an arrangement according to *uses* is also observable. We have, for instance, in pretty near approximation one to another, the whole range of textile goods—from coarse flannels and thick woollens to gorgeous ribbons and delicate laces; in another department are miscellaneous articles of dress, such as artificial flowers, feathers, stays, wigs, shoes, boots, furriery, hats, hosiery, gloves, &c.; musical instruments have a department to themselves; costly articles of various kinds are collected at the "Parisian" or western end, including clocks, watches, jewellery, bronzes, porcelain, weapons, lamps, painted glass, &c.; along the south side are household furniture and chemicals, in two great divisions; while the east end is chiefly occupied by metal work and machinery.—The difficulties which the arranger of this collection had to overcome, and the wavering balance of his opinions, may be read by a glance at the engraved plan. Our Hyde Park Committee or Managers will find the classification of their treasures not among the least of their weighty difficulties.

The *Birmingham* Exposition of Industry, opened in September, 1849, was one of a peculiarly interesting character; for the town of Birmingham naturally contributed towards it more largely than any other town, and Birmingham carries on a greater variety of manufactures than any other town (perhaps) in the kingdom. This industrial display was planned to take place at the same time as the meeting of the British Association at Birmingham; and there could hardly be a happier mode of establishing the union and mutuality of science and art. It was held at Bingley House, in Broad-street, which was fitted up with a long array of exhibition-rooms. Members of the British Association were admitted free: other visitors paid a charge of one shilling each; but arrangements were made for admitting schools and bodies of workmen at much lower prices.

The *electro-plate* which now constitutes such an important department of Birmingham manufactures formed one of the most attractive portions of the exposition. If regarded as a substitute for solid silver goods, this beautiful new product would have the bad character of being a sham—a mere coating of costly metal on a substratum of cheaper metal; but if we regard it as an improvement on the silver-plating of past times, its true character comes out at once: both are examples of coating copper or some other metal with silver; but the electro process has shown itself to be far the better of the two. The old massive but clumsy tea-service, with its heavy style of ornament, is superseded by a lighter and more graceful production, in which the utmost delicacy of decoration is quite compatible with soundness of workmanship. In an another article, too, viz., *papier maché*, Birmingham has made similar advances within the last few years.

All the most distinguished manufacturers contributed towards the Birmingham collection. The metal-work for church decoration, exhibited by Messrs. Hardman, were strikingly illustrative of a branch of art at present in high favour. The castings in bronze and iron were beautifully executed, showing that Birmingham has risen nearly, if not quite, to a level with the celebrated Berlin iron-founders. Among the specimens exhibited in this department were a pair of richly cast gates for the Fitzwilliam Museum, a chandelier for her Majesty, and a tripod (in imitation of one of those submerged at Pompeii) for the Duke of Sutherland. An elegant combination of brass-work with porcelain and with turquoise-glass formed the material of many specimens exhibited—a material which many of our readers may have seen as applied to fanciful ornamental productions. Stamped brass-work is now becoming extensively employed in house-fittings and furniture; and Birmingham, with great propriety, exhibited the skill which she has attained in this art. An instructive feature in the exhibition was afforded by a series of specimens in porcelain and pottery, designed to illustrate the progress of the plastic arts in this country. First came a group of beer-mugs and drinking-jugs, made in the time of Queen Elizabeth, of coarse clay covered with brown glaze; then came a candlestick and drinking cups, of a somewhat later date; then several specimens of the date of William and Mary, glazed with salt instead of with lead; then a collection of cups, plates, tureens, and other articles, made in the time of George II., with light-coloured ornaments in relief on a dark ground; then the improved ware of the latter half of the last century, when Dorsetshire clay came into extensive use, and when improved modes of glazing were adopted: and lastly, the exquisite productions which resulted from the liberality, the ingenuity, and the enterprise of

Wedgwood. Such a serial collection as the one here alluded to forms the best history of the department of mechanical art to which it relates. The modern productions of the Staffordshire Potteries were of course amply represented at the Birmingham Exposition. Of the miscellaneous iron manufactures, any one who knows Birmingham and its industry may easily conceive how richly they were illustrated on this occasion—stoves and grates, fenders and fire-furniture, cast-iron glass-frames and tables, hat-holders and umbrella-stands, letter-boxes and letter-plates, tea-urns and coal-vases, gas-fittings, files, cutlery, screws, weighing-machines, locks, keys, hinges, tools, springs, latches, wire, steel pens, gun-barrels—all that iron can be supposed fitted to produce (and a great deal that we could hardly dream to be made of such a material) were here displayed. Engineering did not fail to put forth its claims to admiration, in steam-engines, paper-making machines, ticket-marking machines for railways, Baranowski's ready-reckoning machines, tube-rolling machines, and a multitude of others. We cannot pass over the mention of tubes and pipes, which are made in such incalculable quantities, and of such various materials, in Birmingham, without quoting a pleasant scrap from the *Times* relating to the *sanitary* merits of pipes :—" Pipes appear to be the order of the day. Pipes to let pure water in—pipes to carry foul water out—pipes for warming, drainage, ventilation—pipes to bring in gas for burning—pipes to carry off the products of combustion—pipes to the rich man's marble bath-room—pipes to the poor man's brick-paved kitchen—pipes for the fountains of St. James's—and pipes for the stinking cesspools of St. Giles's. For ornament and pleasure —for economy and cleanliness—for health and comfort—for arresting conflagration and extinguishing pestilence—pipes ! The whole sanitary question, indeed, may be regarded as little more than a question of pipes."

The Birmingham Exposition was entirely successful. Nearly 100,000 persons visited it. Free tickets were granted to the pupils of the School of Design, to many school children, and to a large number of work-people. It is an instructive proof that most of the visitors were busily-employed persons, who could only snatch an hour or two to make this pleasant visit, that by far the greater number of persons assembled at one time was between six and eight o'clock in the evening.

The *Society of Arts* has, within the last two or three years, done much to foster a spirit of generous emulation in productive industry, by forming collections of manufactures for exhibition. In 1849 there was one such display, notable for the great beauty and variety of the specimens sent by our leading manufacturers. But the year 1850 has been marked by the unique *Mediæval Exhibition,* which we must not pass over without a brief notice.

The Council solicited in all quarters, for the loan of specimens of middle-age art and manufactures, for a limited period ; and this request was responded to most liberally. Never before was there such a collection displayed to the British public generally ; for it contained the gems of numerous private collections. There were the most exquisite specimens of metal work, in casting, chiselling, engraving, chasing, damascening, embossing, and pouncing ; the metals being gold, silver, copper, brass, pewter, zinc, bronze, iron, and steel. There were beautiful carvings in box-wood, ivory, alabaster, marble, sardonyx, jasper, and agate. There were enamels and incrustations of the most elaborate description. There were clocks and watches of middle-age workmanship ; and there were various specimens of armour and weapons, notable for their high finish. The porcelain and pottery arts were represented by Della Robbia ware, Majolica ware, old Flemish stone ware, Palissy ware, Böttcher ware, and other kinds which exhibit artistic or manipulative skill. The specimens of glass ware—Greek, Etruscan, Roman, Venetian, and early German—were highly curious. Tapestry, embroidery, lace, embossed leathers, mosaic—all tended to swell the list of Mediæval specimens in this highly interesting exhibition.

The Exhibition of *Modern* Industry, displayed at the Society of Arts at the same time, does not call for mnch remark. It consisted of a small number of specimens in silks, damasks, lace, velvet, poplin, shawls, carpets, papier maché, marqueteric, glass, castings, carvings, modellings, &c.

Dublin has claimed its right to consideration as the centre of an Industrial Exposition. During the month of July in the present year, (1850) a very interesting collection of manufactured products was exhibited, under the auspices of the Royal Dublin Society, and in the rooms belonging to that body. The house of the Society is a handsome structure, with a range of eleven Italian windows in width, and having a garden and lawn in the rear. All the principal rooms were appropriated to the reception of the specimens: such as the gallery, the Agricultural Museum, the Board Room, the Corridor, the Hall, the Library, the Grand Staircase, the Schools, the six rooms occupied as a Museum, &c.; besides which there were an iron house and a wooden-shed constructed on the lawn. Every apartment was divided into sections; every section was marked off into stalls or tables; and every specimen was numbered and catalogued.

The catalogue prepared by the Society is an unusually complete and full one: so good, indeed, that we may almost regret that it had only a temporary utility, terminating when the exhibition was brought to a conclusion. It may be hoped that a few copies of this catalogue will be preserved, for the sake of furnishing hints to future catalogue makers in respect to industrial collections. It is an octavo pamphlet of about 170 pages. At the beginning are thirteen lithographed plans, showing the exact arrangement of the several floors of the building. Next comes the catalogued enumeration of all the specimens exhibited, numbered in order from 1 to 2,850. In most cases, all the specimens sent by one contributor are numbered consecutively, grouped into one section, and entered in the same part of the catalogue: where the name, occupation, and address of the contributor are given. Near the the end of the catalogue is an alphabetical list of contributors' or exhibitors' names; with the room, the section, and the table appropriated to each person's contributions, and the number of the specimen which begins the group belonging to that person. Lastly, there is a classified list of the trades represented at the exposition, and an alphabetical list of all the persons who sent specimens illustrative of each trade.

This classified list shows how wide was the range embraced by this industrial display: for it includes the following headings—silks, linens, damasks, muslins, and chintzes; fringe and coach lace; carpets and rugs; woollen drapery; hosiery; hats; fancy work; lace and embroidery; hair work; leather; oil-cloth; matting; cabinet-making; picture frames; carving and turning; lamps and lustres; glass; marble; porcelain and pottery; watches and clocks; precious metals; electrotypes; iron work; machines and engines; fire-arms; musical instruments; philosophical and mathematical instruments; agricultural and horticultural implements; carriages; paper hangings; printing; bookbinding; soap and candles; perfumery; ink and blacking &c. The raw materials of manufactures did not form part of the collection.

Many of the specimens exhibited could only be ranked as trinkets or curiosities; but by far the larger number bore immediately on the present state of the industrial arts, especially in Ireland. Irish poplins and Irish linens were fittingly and worthily represented; and so were the damasks, taberets, and gold-tissued poplins, which are manufactured in small quantity but of high excellence in Dublin. The specimens of Limerick lace were especially interesting; for the art of lace-making was not known in that locality until about twenty years ago, whereas it is now an important adjunct to the industry of the place. In 1829 a few young women were taken over to Limerick, to teach this art to various females in the humbler grades of society; and there are now at least one thousand women and girls who are earning at the trade a living for themselves and their families, Messrs. Lambert and Bury, lace manufacturers at Limerick, employ at the present time about four hundred hands in their own establishment.—If Ireland and its people, its rulers and its agitators, would eschew politics once now and then, and try to find a home for manufactures within that beautiful country, we should not hear so much of starvation and of wrangling as we now do. The Limerick lace-manufacture is a case in point; and another is furnished by the muslin-embroidery which is carried on so extensively in the neighbourhood of Belfast and Coleraine, where there are many thousand females employed at this work by Glasgow firms; immense quantities of embroidered Scotch muslins are woven in Scotland, but embroidered in Ireland.

Many of the articles exhibited were said to be "French materials, made up in Dublin;" but many were undoubtedly Irish, both in materials and in manufacture; among which were ornamental articles made of Irish bog-oak. There were some copies or imitations of Irish antique ornaments, made from iron ore and gems found on the Marquis of Waterford's estate. There were sets of tea-trays, elaborately carved fire-screens, and small statuettes, in Irish bog-yew. Many of the exhibitors drew attention to the fact, that the specimens exhibited by them, belonged to branches of manufacture, which, though long and familiarly known in England, are yet new to Ireland; among such is wire-woven cloth for paper-making. Dr. Bagot, of Dublin, sent a few remarkable contributions, interesting in an indirect manner to manufactures and manufacturers. One was a collection of fuel-balls, used by the peasantry of Tipperary; they are usually made by women, who manufacture them by mixing together culm and yellow clay in proper proportions, and, whilst gradually adding a sufficiency of water, work the ingredients into a mass with their bare feet; the mass is then formed into balls, which, when dry, are ready to use as fuel. Another contribution by Dr. Bagot was a curious one, consisting of seven specimens of "cod-liver oil," procured from different quarters. This oil is now extensively employed on account of its powerful medicinal qualities; and the specimens were exhibited, to shew how great is the difficulty of knowing good from bad qualities, and how much deception has crept into this branch of commerce; they were charged from twenty-four shillings to forty-four shillings per gallon, and some of them, (among which was the most costly specimen), contained no cod-liver oil whatever, while others were adulterated with three-fourths their bulk of other and commoner kinds of oil.

It would carry us into too wide a field were we to enter further into the arrangement and contents of the Dublin Exposition. Suffice it to say that many of the leading English manufacturers exhibited their strength in the excellence of the specimens submitted:—Hunt and Roskell their costly works in the precious metals; Elkingtons their wonderful productions in electro-plate; the Copelands, the Mintons, the Ridgways, the Chamberlains, their exquisite works in porcelain; Houldsworths, their beautiful Manchester silk goods; Webbs, their curious hair-cloth damasks; Swainsons their chintzes from Preston; Chubbs, their labyrinthine patent locks; Whitworths, their planing and screw-cutting machines; the Ransomes and the Croskills their agricultural implements, &c.

The *Devonport* Mechanics Institute has honourably followed in the path marked out by its northern compeers. A new Hall and Subscription Rooms have been recently opened in that town; and it was thought that a graceful and fitting mode of celebrating the event would be by assembling together specimens of art

KNIGHT'S CYCLOPÆDIA

OF THE

INDUSTRY OF ALL NATIONS.

A'BACUS, in architecture, is the level tablet, formed on the enriched capital of a column, to support the horizontal entablature.

A'BACUS, an instrument employed to facilitate arithmetical calculations. One variety consists of a frame, traversed by stiff wires, on which beads or counters are strung so as to move easily; the beads on the first right hand row are units, those on the next tens, and so on. Such instruments are not now much employed.

ABANDONMENT. Before a person who has insured a ship or goods can demand from an insurer or underwriter the stipulated compensation for a total loss of such ship or goods, he must *abandon* or relinquish to the insurer all his interest in any part of the property which may be saved.

ABATTOIR. An abattoir, in France, is a slaughter-house, in a form which was first adopted at Paris in 1810. There are three on the north side of Paris, and two on the south side, not far from the barriers, and about two miles from the centre of the city. The cattle markets for the supply of Paris are several miles distant, and the cattle are driven from them round the exterior boulevards to the abattoirs, and consequently do not enter the city. At one of the abattoirs each butcher has his slaughter-house, a place for keeping the meat, an iron rack for fat, pans for melting it, and a place with convenience for giving cattle hay and water, and where they may be kept before being slaughtered. A fixed sum is charged for this accommodation, and in 1843 the fee was 6 francs for each ox, 4 francs for a cow, 2 francs for a calf, and 10 cents for a sheep. The income of the establishment, arising from these fees, the sale of manure, &c., was above 48,000*l.* in 1842. An inspector is appointed at each abattoir, and means are taken to prevent unwholesome meat being sold. There are slaughter-houses under public regulations in most of the continental cities; and those of New York and Philadelphia, and some other of the cities of the American Union, are, it is said, placed on a similar footing.

The great cattle-market in Smithfield, for the supply of London, has existed above five centuries, but the spot was originally a piece of waste ground beyond the city, instead of being, as at present, surrounded by a dense population. The cattle sold in Smithfield Market amount annually to about 180,000, and the sheep to about 1,500,000, and at least this number are annually slaughtered within the limits of the metropolis. There are slaughtermen who kill for other butchers frequently above a hundred head of cattle, and perhaps five or six hundred sheep, every week; many butchers kill for themselves to a considerable extent, and there are few who have not accommodation for slaughtering and dressing a few sheep, either in the cellar underneath their shop, or in the rear of their premises. The slaughter houses, for sheep, in Newgate market, many of which are in cellars, and in Warwick-lane, are close to Newgate-street, and within a hundred and fifty yards of Ludgate-street, two of the great thoroughfares of London.

During the last few years searching enquiries have been made respecting the practicability of removing Smithfield market, and establishing abattoirs for the metropolis in a less crowded situation. The city authorities, who levy considerable tolls in the market, have resisted all proposals for removing it to any place beyond their jurisdiction; and the contest has been (and still is) whether such a removal, to Islington or elsewhere, shall take place; or whether Smithfield market itself shall be enlarged and improved. An opulent projector, some years ago, expended upwards of 100,000*l.* in the formation of a cattle market in Lower Islington; twenty-two acres of land were appropriated; and the market was efficiently provided with counting-houses, offices, sheds, lairs, pens, wells, and everything requisite for a market suitable for twice as many cattle as are accommodated at Smithfield; while plans were arranged for abattoirs adjoining. The market was opened in 1833; but this vast scheme failed, from various causes, and the well-arranged area has ever since remained wholly useless. To revive this market, is one among many recent projects.

In 1847 a Committee of the House of Commons enquired into the subject of Smithfield market. The evidence was published, but without any report on the part of the Committee. Among the items of evidence it was stated that the largest Smithfield market-day (down to the end of 1846) occurred in 1844: on one day in that year there were 5,633 cattle and 39,920 sheep exposed for sale at Smithfield. In the voluminous evidence, extending to 400 pages, every part of the subject received much elucidation, and many details were given concerning the abattoirs of Paris; but it became afterwards known that the Committee were too much puzzled by conflicting evidence to form any decided opinion on the main question submitted to them.

Early in the session of 1849 Mr. Mackinnon moved for the appointment of a committee to enquire into the state of Smithfield market, with a view either to its removal or its improvement. There was some opposition to the motion; but the committee was eventually appointed, and evidence was taken, bearing on the subject. About the middle of the year the report of the committee was presented; in which it was stated that Smithfield market, from its deficiency in size, and from the inconvenience which was thereby created, ought to be abolished; that the area of a new market, its site and locality, should be determined by the authorities of the city of London, or, if they declined, by the government; that of the 5¼ acres which Smithfield occupies, 4 acres should be converted into a pleasant open square, and the remaining 1¼ acres devoted to a range of handsome buildings, the rents of which would probably go far to make up for the loss of tolls sustained by the corporation. In a long debate, Mr. Mackinnon pressed upon the government the adoption of plans in conformity with the report; but the session passed away without further results.

In the early part of 1850 a commission investigated the whole subject, and reported on the propriety of removing the market from Smithfield; but no legislative steps have yet been taken; and the city authorities are still planning various improvements (to cost 500,000*l.*) in the existing market. Whilst the authorities of the City of London are thus deliberating how they can best preserve a profitable nuisance, the city of Edinburgh is building an abattoir, that may be a model to municipalities who concern themselves for public good.

ABERBROTHWICK, or ARBROATH, is a sea-port town in Forfarshire, Scotland, at the mouth of the small river Brothock. The principal manufactures are, yarn spun from flax and hemp, canvas, brown and bleached linen, leather, cast-iron, and bone-dust. In the town and suburbs there are 16 spinning-mills, which are driven by the river. About 106 vessels belonged to the port in 1849. There is a harbour-basin, faced with stone; and there are railways from Arbroath to Forfar and Aberdeen, and from Arbroath to Dundee and Perth.

ABERDEEN is situated on the river Dee, Scotland, where it is discharged into the German Ocean. *Old* Aberdeen is on the south bank: *New* Aberdeen on the north; and the two together had, in 1849, a population of about 73,000. The harbour is spacious, and is rendered safe by a pier of granite on the north side of the Dee, which extends into the German Ocean.

Aberdeen is a place of large trade, with many manufactures of cotton, linen, and woollen; extensive iron-works, ship-building yards, (some for large steam-vessels,) and manufactures of most of the articles connected with ships and ship-building. The number of sailing vessels registered at Aberdeen, in January, 1850, was 368, with a tonnage of 62,234. There are upwards of 4,000 vessels entered inwards and cleared outwards annually. There are fine fleets of steamers to London, Leith, and Inverness. The foreign commerce is chiefly with North America, the East Indies, West Indies, Mediterranean, and Baltic. Several ships were formerly employed in whale-fishing, but that trade has entirely ceased. The rivers Dee and Don supply a large quantity of salmon, which are exported to London and elsewhere. The value of the Aberdeen granite, shipped to London and other places, has sometimes exceeded 40,000*l.* a year. A granite-polishing work has been lately established.

ABERDEENSHIRE, Scotland, is chiefly remarkable, in an industrial point of view, for the exhaustless supply of granite which it yields. This granite is frequently found disintegrated, at least in so friable a state as to be easily dug into by the pickaxe and spade;

yet large blocks of fine building stone are frequently quarried in the midst of a mass of disintegrated rock. The rivers Dee and Don supply large quantities of excellent salmon. The Aberdeenshire canal runs from Aberdeen to Inverury; the chief traffic is in lime, coal, dung, bones, and bark, carried up; and stone, slate, grain, and meal brought down. The Aberdeen railway only touches the county; the Great North of Scotland Railway (if constructed) will traverse it. About 10,000 acres of the county are covered with wood, such as birch, alder, poplar, and mountain ash. The planted woods are chiefly larch and Scotch firs. The fir timber of the forest of Mar is, for size and quality, the first in the British Islands. The quantity of cultivated land is but small.

The chief animals reared are cattle, sheep, and horses, considerable numbers of which are despatched to London by steamers, which may often be seen a little way below the Tower. The cultivation of turnips has been greatly extended in consequence of the facilities afforded by steam navigation for conveying fat cattle to the London market, and the consequent increase of stock.

ABIES, is the botanical name for the invaluable genus of *Fir* trees. There are many well-known species. The *Abies Picea*, or Silver Fir, is a native of the mountains of the middle and south of Europe, in stony, dry, exposed situations. Planks of indifferent quality, on account of their softness, are sawn from its trunk, which also yields Burgundy pitch and Strasburg turpentine. *Abies Balsamea*, the Balm of Gilead Fir, is found in the cold parts of North America; it yields a clear transparent greenish-yellow turpentine, which is commonly known under the name of *Canadian Balsam*. *Abies Webbiana* is a lofty tree, whose wood seems to be valuable; in India it is used by plane-makers. *Abies Canadensis*, or Hemlock Spruce Fir, is a noble species, rising to the height of seventy or eighty feet. The wood is of little value, being neither sound nor durable: it is chiefly employed for the manufacture of laths and for coarse in-door work. The bark is exceedingly valuable for tanning; mixed with oak bark, it is said to be much better than oak bark alone. A great deal of the Essence of Spruce is extracted from the shoots of this species. *Abies excelsa*, the Norway Spruce Fir, is a native of the mountainous parts of the north of Europe, where it sometimes constitutes, as in Norway, the principal timber. The wood is of a white colour, of a fine even grain, and very durable; in the market it is known under the name of White or Christiana Deal. *Abies alba*, the White Spruce Fir, is found in the colder regions of North America. The timber is of inferior quality. From the fibres of the root, macerated in water, the Canadians prepare the thread with which they sew together the birch bark that forms their canoes. Its resin is also used to render the seams water-tight. The bark is said to be occasionally used for tanning. *Abies nigra*, the Black or Red Spruce Fir, is a native of the most inclement regions of North America. From its young branches is extracted the Essence of Spruce, so well known as a useful antiscorbutic in long voyages. *Abies Douglasii*, the Douglas Fir, is found in immense forests in North-West America. The young branches have their bark filled with receptacles of resin, as in the Balm of Gilead. The timber is heavy, firm, of as deep a colour as yew, with very few knots, and not in the least liable to warp. *Abies Larix*, the common Larch Fir, is a native of the mountains of the middle of Europe, of Russia and Siberia. It grows with great rapidity, is subject to very few accidents, transplants with little risk, and produces timber of great excellence and value, not only for domestic but for naval purposes. In mountainous districts in Scotland the Dukes of Athol have planted it in immense quantities; and it appears, from a report of one of those noblemen to the Horticultural Society, that in situations 1,500 to 1,600 feet above the level of the sea, he has felled trees, eighty years old, that have each yielded six loads of the finest timber. From the boiled inner bark, mixed with rye-flour, and afterwards buried for a few hours in the snow, the hardy Siberian hunters prepare a sort of leaven. The bark is nearly as valuable to the tanner as oak-bark; it also produces the substance called Venice Turpentine, which flows in abundance when the lower part of the trunk of old trees is wounded. A sort of manna, called Briançon Manna, exudes from its leaves in the form of a white flocculent substance, which finally becomes concreted into small lumps. *Abies Cedrus*, the Cedar of Lebanon Fir, grows in Syria and the Taurus. According to Labillardière, a French traveller in Syria, the largest of those now remaining on Lebanon is, at least, 9 feet in diameter; the trees are held in great veneration. *Abies Deodara*, the Sacred Indian Fir, is a large tree, with a trunk about 4 feet in diameter. The wood is extremely durable, and so resinous that laths made of it are used for candles. Spars of it have been taken out of Indian temples, known to have been erected from 200 to 400 years, uninjured, except in those parts which originally were sap-wood. Mr. Moorcroft procured specimens from the starlings of a bridge in Ladakh, where it had been exposed to the water for nearly 400 years. Mr. Lambert says, that its wood takes an excellent polish, being very close-grained.

The genus of resinous plants called *Abies*, which we have thus described, comprehends many forest trees of great importance. Some of them, such as the Larch, the Norway Spruce, the Silver Fir, and the Balm of Gilead, are raised in nurseries in the open ground, in large quantities, for the supply of our plantations; others, such as the Cedar of Lebanon and the Douglas Fir, are procured in much less abundance, and are treated with more care, being usually kept in pots until they are finally committed to the earth in the situation they may be subsequently destined to occupy.

ABINGDON, in Berkshire, is situated at the junction of the Ock and the Thames. The trade consists of malting, hemp-dressing, and sack-cloth and sail-cloth making; besides which there are two large clothing factories. The corn-market is large. Capacious wharfs and warehouses have been erected at the entrance of the Wilts and Berks canal into the Thames. The Oxford branch of the Great Western Railway passes by Abingdon, near which there is a station.

ABORI'GINES, a term by which we denote the primitive inhabitants of a country. Thus, to take one of the most striking instances, when the continent and islands of America were discovered, they were found to be inhabited by various races of people, of whose immigration into those regions we have no historical accounts. All the tribes, then, of North America may, for the present, be considered as aborigines. But the word aborigines has of late come into general use to express the natives of various parts of the world in which Europeans have settled ; but it seems to be limited or to be nearly limited to such natives as are barbarous, and do not cultivate the ground, and have no settled habitations. The aborigines of Australasia and Van Diemen's Land (if there are any left in Van Diemen's Land) are so called as being savages, though the name may be applied with equal propriety to cultivators of the ground. Some benevolent people suppose that aborigines, who are not cultivators of the ground, may become civilized like Europeans. But it has not yet been proved satisfactorily that this change can be effected in any large numbers; and if it can be effected it is an essential condition that the aborigines must give up their present mode of life and adopt that of the settlers. The New Zealanders, a people of natural industry and acuteness, will perhaps furnish the most striking example of the dominant influence of civilization. But such a change is not easy: even in the United States of North America it has been only partially effected. The wide expanse of country between the Mississipi and the Atlantic is now nearly cleared of the aborigines, and the white man, who covets the possession of land, will follow up his victory till he has occupied every portion of the continent which he finds suitable for cultivation. The red man must become a cultivator, or he must retire to places where the white man does not think it worth his while to follow him. The savage aborigines do not pass from what we call barbarism to what we call civilization without being subjected to the force of external circumstances, that is, the presence among them of settlers or conquerors. There is no more reason for supposing that huntsmen will change their mode of life, such as it is, without being compelled, than that agricultural people will change theirs. As contributors to the Industry of Nations, the aborigines of North America are important auxiliaries to the commercial skill of the European. The fur trade is supported by the hardihood and sagacity of the Indian hunters and trappers. See Fur Trade.

ABOUSAMBUL, or IPSAMBUL, a place remarkable for containing two of the most perfect specimens of Egyptian rock-cut temples adorned with sculptures. These excavations are in Nubia, on the west side of the Nile. The smaller temple has on each side of the doorway, three standing colossal figures, about 30 feet high, cut out of the rock and deep sunk in niches, to the back part of which they are attached by a portion of the rock that has been allowed to remain. The figures are in a standing position, with one foot advanced, and looking towards the river. On each side of the larger figures stand smaller ones, from four to six feet high. The larger temple has four enormous sitting colossi in front, which are the largest in all Egypt or Nubia. Each of these figures is 25 feet 4 inche across the shoulders, the face 7 feet long, the nose 2 feet 8 inches, the beard 5 feet 6 inches; the whole height as it sits is about 50 feet, besides the cap, which is 14 feet high. Only two of these monsters are in sight; the others are buried in the sand. Over the door there is a figure in relief of Osiris, 20 feet high, with two colossal figures, one on each side looking towards it.

ABRUZZO. There are in the kingdom of Naples three divisions called respectively *Abruzzo Ultra* 1, *Abruzzo Ultra* 2, and *Abruzzo Citra*. They contain together about 800,000 inhabitants. Aquila, the chief town of Abruzzo Ultra 1, has manufactures of paper, stockings, and leather. The lake of Celano is in this province. The Emperor Claudius undertook a great work for the purpose of draining the lake, or at least preventing it from doing damage by overflowing. Claudius made a canal 3 miles long, partly by perforating and partly by cutting down a mountain: it was finished in eleven years, 30,000 men having been constantly employed thereon.

The natives of the highlands of Abruzzo are chiefly employed in rearing and tending sheep, numerous flocks of which, after feeding on the mountain pastures during summer, migrate to the plains of Puglia at the approach of winter. The shepherds are generally accompanied by their wives and children in these yearly migrations to and from the mountains, and by their large white dogs, which are very fierce to strangers. The sheep's milk is used to make cheese, the wool is an important article of trade, and the skins are exported in great quantities to the Levant. The shepherds also are clothed in them, and wear sandals of untanned leather, fastened with small cords, round the leg. The breed of merino sheep has been introduced into the Abruzzi. The lower parts of the Abruzzi have a productive soil, and export a considerable amount of grain, oil, and almonds: they also produce some cotton.

ABUSHIRE, or BUSHIRE, a sea-port and commercial town in the province of Farsistan, Persia, is situated on the north-east coast of the Persian Gulf. Ships of about 300 tons burthen can lie in the inner roads about six miles north from the town, and ships of larger burthen in 25 feet of water, three or four miles west from the town. Abushire is the emporium of a large commerce between the East Indies and Persia, its merchants supplying almost all Persia with Indian commodities as well as with many of those of Europe, and exporting in return the productions of Persia and Turkey to the East Indies and to Europe. Of the imports from India the most important are indigo, sugar, and spices; of the Persian exports, raw silk is the most important.

ABUTMENT, in building and machinery, is that which receives the end of and gives support to any thing having a tendency to spread. The piers or mounds on or against which an arch that is less than a semicircle, or a series of such arches, rests, are abutments; while the piers at the extremities of a bridge, of whatever form its arch or arches may be, are always termed its abutments. In machinery also the word has a similar meaning, as applied to a fixed point from which resistance or reaction is obtained. Springs, whether used, as in a watch, to impel machinery, or, as in the various kinds of spring-balance, to measure or control force, must have their abutments, as also must all machines in which power is transmitted by means of screws. The name is applied in carpentry to a joint in which the end of one piece of timber is joined to the side of another, so that their fibres form an angle with each other.

ABYSSINIA. This African country is an elevated table-land, lying between 8° 30′ and 15° 40′ N. lat. and between 35° and 42° E. long. The north-eastern edge of the table-land is directed towards the Red Sea, and is from 30 to 60 miles from its shores; the other or inland edges slope away to a lower level on every side; so that if the surrounding part of Africa were covered with water to the depth of a few hundred feet, the whole of Abyssinia would form an island. Though Abyssinia is situated between the tropics, its productions rather resemble those of the temperate than of the torrid zone. Few of the grains of India are found here. The other grains are wheat, barley, oats, Indian corn, durrha, and tokussa. There are some small plantations of coffee; and cotton is grown in the lower parts of the country. Excellent grapes grow at the foot of the rocky masses to the east of Lake Zána. The domestic animals consist of horses, cattle, sheep, goats, mules and asses. There is also the black sheep, which seems to be peculiar to this region; the wool is of a black colour, and about eighteen inches in length. The people take great care of these animals, lest they should get too fat, for then the wool falls off; they are placed on frames, cleaned every day with water, and fed with roasted barley and other food. A skin of good quality is sold for a dollar and upwards, which is a very large sum in that country. These skins are worn by the warriors. Wild animals are very numerous.

Gold has occasionally been found in Abyssinia. The mountains of Lasta are rich in iron-ore, which is worked, and appears to be of good quality. The great salt-plain which lies between the Red Sea and the table-land of Tigré belongs partly to the sovereign of Tigré, and immense quantities of rock-salt are annually taken from it and imported to all parts of the country, as it is not only used for culinary purposes, but also as currency. Large quantities of salt, taken from the salt lake Assal, are annually imported into Shoa, as salt is not found on the table land. Sulphur is found at several places.

The Abyssinians have made tolerable progress in manufactures. The best article is tanned skins, which are used for bedding or for tents: an important article, on account of the numerous caravans which traverse the country. Shields made of the hides of elephants or rhinoceroses are also good. Axes and ploughshares, as well as spear heads, are made at several places; but knives, sword-blades, scissors, and razors, are only made at Gondar and at Kiratza. At Gondar guns are made, but only by some Greeks, not by the natives. Large quantities of coarse cotton-cloth are made in several parts of the country by women, and a finer kind, with a red or blue border, for the more wealthy classes of society. The silk manufactures are limited to some embroidery, made by Mohammedans and worn by their women, and to blue strings, which are worn on the neck by all Christians, as a mark of distinction from Mohammedans or heathens. A coarse stuff is made from the wool and hair of the black sheep and goats, which is also employed in making a kind of counterpanes. Coarse black pottery is made in every part of the country. Printing has not yet been introduced into Abyssinia: so that the copying of manuscripts forms a distinct branch of industry.

Abyssinia has no immediate intercourse with seafaring nations, but its products are carried either to Massówa on the Red Sea, or to Tajurrah on the gulf of Aden. Massówa is the harbour of Tigré and Amhára; and Tajurrah the harbour of Shoa. Nearly all the articles imported into Massówa go to Abyssinia. They comprise raw cotton, pepper, blue and red cotton-cloth, the threads of which are unravelled and woven into the borders of the cloths of native manufacture, raw silk dyed blue, white cambrics, a small quantity of glazed silks, and some common velvet, glass pearls, linen shirts, common red-cloth, some articles of glass, common razors, sword-blades, spica celtica, small parcels of red or green morocco leather, zinc, common Turkish carpets, bottles of a peculiar shape, of which large numbers are used in Abyssinia, and a large quantity of Persian tobacco. The bulk of the goods imported into Abyssinia is probably consumed there, but some of them find their way into the interior of Africa to supply other countries. They are exchanged for the produce of these countries at Báso, where a market is held weekly during the season, which lasts about eight months in the year. The merchants bring from the southern countries slaves, ivory, coffee, civet, gold, cloth, iron, and cattle.

ACA'CIA, a very extensive genus of trees or shrubby plants, inhabiting the tropical parts of both the Old and New World. Some of the species produce *catechu* and *gum-arabic;* the bark of others yields a large quantity of *tannin*, which, in the form of an extract, is annually imported from Van Diemen's Land in considerable quantity. The *catechu* acacia is a tree with a tolerably high and stout stem, found in mountainous places in the East Indies, especially in Bengal and Coromandel; its unripe pods and wood yield, by decoction, one of the sorts of catechu, or terra-japonica, of the shops, a powerfully astringent substance, formerly thought to be a kind of earth. The *Acacia Arabica* or gum-arabic tree, is an inhabitant of the East Indies, Arabia, and Abyssinia, where it forms a tree thirteen or fourteen feet high. This is one of the plants that yield the useful substance called gum-arabic, which is procured by wounding the bark; after which the sap runs out, and hardens in transparent lumps, of various figures, very similar to the concretions found upon the bark of the cherry-tree in this country. Gum-arabic is also produced abundantly by some of the species nearly related to this. Gum-senegal is the produce of a distinct species called *Acacia Senegal*, found in Arabia and the interior of Africa. From this tree are said, by some, to be procured the pods called *bablach* in the continental drug-shops.

ACANTHUS, is the sculptured leaf which is the distinguishing characteristic of the capital of the Corinthian column. The same leaf, however, is used occasionally in other foliated capitals, as well as for the enrichment of modillions, of mouldings, and of vases. This ornament, in the Roman models, is fuller and broader than it is in the Greek.

ACAPU'LCO, a city and port in the republic of Mexico, about 183 miles S. S.W. from the capital; the port is capable of containing 500 ships, and is deep enough to allow vessels to lie close to the rocks. The city of Mexico communicates with the Pacific by the town of Acapulco, which once had a considerable trade, particularly with Manilla. Under the Spanish dominion a vessel of the largest size used annually to leave Acapulco for Manilla about February or March, loaded with commodities and specie. The vessel returned to Acapulco in August, carrying back muslins, printed calicoes, coarse cotton shirts, porcelain, Chinese jewellery, &c. Its arrival was the signal for a great concourse of merchants to Acapulco, who swelled the population for the time to about 9000. The commerce of the town has however since declined. The exports are cochineal, indigo, silver, and skins. Acapulco is not far from the Isthmus of Tehuantepec, one of the narrow tracts by which Central America is crossed on the route from the Atlantic to the Pacific. But the great commercial routes to California are now (1850) being formed further southward, viz., a combined steam-boat and land-route viâ Nicaragua, and a railway viâ Panama.

ACCO'RDION, a musical instrument, which was introduced into England from Germany about the year 1828. It is in the form of a small oblong box. The interior exhibits a row of very small elastic metallic springs, fixed at one end in a plate of metal, so that they may vibrate freely. The upper and lower parts of the box are united by a folding apparatus, or bellows, which supplies the air required to put the springs into vibration; and to these the air is admitted by means of valves acted on by keys, in the manner of an organ. There is also a very simple contrivance by which a base note, or drone, may be added, at the discretion of the performer. These instruments vary in size and in capabilities: the compass of the most complete is from G, the fourth space in the base staff, to E, the seventh additional space above the treble, including all the semitones; and two or more notes can be played at once. The Chinese are known to possess a musical instrument very similar to this.

ACCRINGTON, is one of the seats of the cotton manufacture in Lancashire. It has grown up from an insignificant village to a town of great importance, in a very few years. In the middle of 1850 there were ten extensive cotton, bleach, dye, and print works; and two more were in process of establishment. Two of these works belonging to Messrs. Hargreaves, employed at that time no fewer than 1600 workpeople; and the whole ten establishments gave occupation to nearly 3000. Nothing illustrates more strikingly the vastness of the cotton manufacture, than the rapid growth of these Lancashire towns.

ACCUMULATION OF POWER. In the coining press, a vast accumulation of force is obtained by means of the fly wheel: the reciprocating motion of a piston connected with a steam-engine communicates, by means of a crank, a continuous circular movement to the fly, and at the same time a reciprocating rectilinear motion vertically to the cylindrical shaft (the stamper) on which the screw is formed. With half a revolution of the fly-wheel the stamper is lifted up, and with the other half it is forced down on the metal, which thus receives at once all the motion accumulated in the fly during an entire revolution.

There are in machinery many such examples of accumulation of power. When a heavy body, like the rammer of a pile-driving machine, descends by the action of gravity during a certain time, and impinges on an object, a shock is produced immensely greater than would result from the mere pressure of the body.

ACER, the botanical name for the different species of *Maple* trees.

The *Acer oblongum*, or oval-leaved maple, is an evergreen tree, of rapid growth, native of the northern parts of India.

The *Acer lævigatum*, or polished maple, is found in the woods of the higher mountains of Nepaul; its timber is used by the inhabitants of Nepaul for rafters, beams, and similar building purposes.

The *Acer Tartaricum*, or Tartarian maple, is an ornamental tree, or rather large bush. From its keys, deprived of their wings, the Calmucks form, by the aid of boiling water, an astringent beverage, which, mixed with an abundance of milk and butter, forms a favourite article of their diet. The wood is hard and white, mixed with brownish veins.

The *Acer striatum*, or striped-bark maple, is a native of North America. Its wood is very white, and is used by the North Americans for inlaying cabinet-work; its shoots afford food to various animals, especially to the moose-deer, in winter and spring, whence it has acquired the name of *moose-wood.*

The *Acer obtusatum*, the Neapolitan maple, is a fine tree, which grows to a height of about 40 feet.

The *Acer campestre*, the common maple, is spread over the greater part of Europe. In England this is either a bush or a small tree, of inelegant appearance; and its wood is of little value, except for the use of the turner, who makes it into cups, bowls, &c. In the southern region of Caucasus, we are told by Pallas that it becomes a tree of handsome aspect, with a trunk as thick as a man's body, and that its wood is so hard as to be in request for the manufacture of musket-stocks.

The *Acer pseudo-plátanus*, the sycamore-maple, flourishes in middle and southern Europe. Although the wood of this species is not particularly valuable, being chiefly used for coarse work, where lightness and toughness are required, yet there is scarcely any more universally cultivated for the sake of the striking effect it produces, whether as a single tree, or planted in avenues, or in masses.

The *Acer Platanoïdes*, the Norway maple, is a fine tree, of North and Central Europe. Its wood is valued for turners' work; from its ascending sap a kind of coarse sugar has been procured.

The *Acer saccharinum*, or sugar maple, grows abundantly in North America. In the autumn the woods of those countries are dyed of a crimson hue by the changing leaves of the sugar maple. The wood is hard, and has a satiny lustre, but it is readily attacked by insects, and is not of much value, except when its grain is accidentally waved, and then it is in request for the cabinet-makers. The saccharine matter contained in its ascending sap is the principal cause of this species being in so much request. From this sap, obtained by tapping the trunk in the spring, during the space of six weeks, a very considerable quantity of a fine brown sugar is procured; as much, it is said, as 33lb. per tree. The sugar maple does not generally succeed very well in England, where it is rarely seen, and where, even when in health, it is not more than 15 or 16 feet high.

ACETATE, a salt resulting from a combination of acetic acid with an alkaline, earthy, metallic, or vegeto-alkaline base—four varieties which may be exemplified by the acetates of soda, lime, lead, and morphia. Although the acetates possess some properties in common, yet, from the very different nature of their bases, they are variously affected by heat; some being merely evaporated, and others wholly decomposed, at high temperatures.

The acetates are a very important class of compounds. Some of them are used in the preparation of acetic acid. The acetate of alumina and the acetate of iron are largely employed by calico-printers; and many of the metallic acetates are used also by them, and by dyers and colour-makers.

ACETIC ACID, or *Acetous Acid*, is the sour part of vinegar, and that to which its peculiar and valuable properties are owing. It is procured, first, by the fermentation of saccharine or sugary matter,—secondly, by the action of heat upon wood; the product of the former constituting *vinegar*, and of the latter *pyroligneous acid*.

1. *Vinegar*. When certain vegetable juices which contain much sugar, such as that of the grape, are fermented, the sugar undergoes the vinous fermentation [FERMENTATION], by which alcohol is produced; and if this process be carried beyond a certain stage, a further fermentation called the acetous fermentation ensues, by which vinegar is produced: so that, in effect, sugar becomes alcohol, and then alcohol becomes vinegar. How this is managed in practice is explained under VINEGAR, where also the peculiar arrangements of the great vinegar-factories are described. Vinegar is, in practice, made from four sources,—wine, malt, sugar, and wood.

Vinegar (or rather Acetic Acid) possesses the usual property of acids to redden vegetable blue colours; it combines with the alkalis, earths, and metallic oxides to form the salts which are termed *acetates*. Vinegar is purified from the sulphuric acid and colouring matter which it contains by distillation; but its smell and taste are then less agreeable, and it is weaker than acetic acid otherwise procured. When vinegar is exposed to a low temperature, it is principally the watery part which freezes.

2. *Pyroligneous Acid*. The second method of obtaining acetic acid is by heating wood, as the dried branches of trees, in hollow iron cylinders, with a proper arrangement of coolers, or condensers, and receivers. Birch and beech are the best woods for yielding it. The pyroligneous acid thus procured is of a dark brown colour, has a strong burnt acid smell, is very sour to the taste, and acts strongly on vegetable blue colours. It contains a quantity of tar and oily matter; from these it is purified, in a considerable degree, by redistillation; and a further purification with lime converts it into a pyrolignite of lime. This pyrolignite, by the chemical action of dilute sulphate of soda, produces acetate of soda, which is a crystalline salt. From these crystals pure acetic acid is produced, by exposing them to the action of sulphuric acid, which combines with the soda of the acetate, and leaves the acetic acid free.

Pyroligneous acid is employed to preserve meat, and to impart to it the smoky flavour usually obtained by drying. Pure acetic acid is used in chemical researches, and especially for preparing various acetates. In a less pure state it is employed in the arts, for preparing acetate or sugar of lead, acetate of copper, or verdigris, and acetate of alumina, which is largely used by calico-printers as a mordant.

ACETIMETER is the name of a kind of hydrometer, used by the Excise authorities in determining the strength of vinegar.

ACETONE, or *Pyro-acetic Spirit*, is a colourless limpid liquid; its odour is peculiar, penetrating, and somewhat aromatic; it mixes in all proportions with alcohol, æther, and oil of turpentine. It is very inflammable, and is not affected by exposure to the air.

ACHARD, FRANZ KARL, born at Berlin, in 1754, died in 1821, was the author of various works, written in German, on experimental physics, chemistry, and agriculture. Achard is however chiefly known for his proposal to extract sugar from beet-root. Another Prussian chemist, Margraff, had discovered the existence of a certain portion of sugar in this root as early as 1747, but deemed his discovery of little practical importance. Achard, on the contrary, described beet-root as 'one of the most bountiful gifts which the divine munificence had awarded to man upon the earth.' The institute of Paris, in 1800, honoured him with a vote of thanks, but reported unfavourably of the practicability of his plan. Napoleon however, in 1812, formed an imperial manufactory at Rambouillet, when the plan of Achard was put in practice, and partly succeeded. Since then the manufacture of sugar from beet-root has been carried on very extensively in France. The manufacture however is a forced one, and therefore of very questionable policy. [BEET: SUGAR.]

ACHROMATIC. [LENS.]

ACIDIMETER. By reversing the mode of using the Alkalimeter, an Acidimeter may be produced, which will determine the strength of the acids employed in commerce or manufactures. [ALKALIMETER.]

ACIDS. The acids are a numerous and important class of chemical bodies. They are generally sour; usually, but not universally, they have great affinity for water, and are readily soluble in it; they change most vegetable blue colours to red; and they unite readily with most alkalis, and with earthy and metallic oxides. Some are natural, some artificial, and some both; some are gaseous, some liquid, and some solid, at common temperatures; some are transparent, and others coloured; some inodorous, and others pungent; some volatile, and others fixed; so that they vary greatly, except in the qualities first named.

No simple or elementary substance has the properties of an acid, and consequently all acids are compounds of two or more of them. In almost every case one of these elements is either oxygen or hydrogen, producing the *oxacids* and the *hydracids*, the former of which are by far the most numerous. In some instances oxygen gives rise to different acids by combining with the same element in various proportions.

Acids occur in all the kingdoms of nature; the phosphoric acids which exist in bone are of animal origin; the citric and the oxalic acids are products of vegetation; the chromic and the arsenic acid enter into the composition of certain minerals; and many of the acids are derivable from two or more of these sources, and are made by chemical agency.

All the acids which are of any importance in the manufacturing arts, will be found described under their proper titles.

ACONITI'NA, a vegetable alkali which exists in *aconite*, in combination with *aconitic acid*. It crystallizes in white grains, and is inodorous, but intensely bitter and acrid. It is obtained and derives its name from the *Aconitum*, or *Wolf's Bane*, the poisonous properties of which are due to the Aconitina. All the parts of this plant are extremely acrid, especially the roots, which are scraped and mixed with food to form a bait for wolves and other savage animals. According to the observations of Orfila, the juice of the leaves introduced into the stomach occasions death in a short time; the root is far more energetic. The poison acts upon the nervous system, especially the brain, producing a sort of frenzy. The use of this dangerous plant is now almost entirely restricted to painful affections of the nerves, and to rheumatic complaints. We are not aware that it is employed in manufactures.

ACORNS were in ancient days more extensively used for food than they are at present. Acorn bread was much eaten both by the Greeks and Romans; and our Saxon ancestors reckoned *mast* or acorns as an important part of their food, especially in years of deficient harvest. When we find, in 'Don Quixote,' that acorns are described as being served after the repast of the goatherd; and that Teresa sends a present of the choicest acorns she could collect to the duchess, we may reasonably conclude that Cervantes had in his thoughts a custom well known among his countrymen. In Greece, Asia Minor, and Barbary, acorns are sold in the streets as food, and are eaten both raw and roasted. The late General Jackson, of the United States, once sent his officers an invitation to a breakfast of acorns, at a time when provisions were scanty. Tolerably good bread may be made from acorns, when shelled, and especially if allowed to germinate before being used, so that part of the farina may become converted into sugar; some persons who have tasted such bread are of opinion that it is very little inferior to oat bread. Acorns, however, are chiefly serviceable in this country as food for swine.

ACOUSTICS, a word derived from the Greek, and signifying the science of sound. The only part of this interesting science which will come within the range of our present volume, is that which determines the particular mode of eliciting sound from the principal musical instruments; for these details we refer to the names of the instruments themselves.

Acoustic instruments for the relief of partially deaf persons, have been invented in considerable number. Dr. Scott's *Soniferon* is a sort of bell-shaped instrument attached to a tube. The bell, instead of resting on its large or open end, is placed horizontally on an upright leg, on which it revolves. The mouth of the bell is covered with a perforated metallic plate; and the interior of the bell is grooved with spiral channels. A pipe of caoutchouc or gutta percha is attached to the bell, and is connected at the other end with a small ivory ear-piece. When a person who is hard of hearing wishes to take part in conversation around a table, the bell is brought opposite the mouth of the speaker, and the hearer places the ivory piece to his ear. It does not differ from other acoustic tubes in its principle, but in its applicability to many persons seated at the same table, and at any distance from the one who is to be primarily benefitted by the invention. [EAR TRUMPET].

ACRE, a measure of land, of different value in the different parts of the United Kingdom. When mentioned generally, the statute or English acre is to be understood. A square whose side is 22 yards long is the tenth part of an acre, which therefore contains 22 × 22 × 10, or 4840 square yards. The chain with which land is measured is 22 yards long; so that ten square chains are one acre. This measure is divided into 4 roods, each rood into 40 perches, so that each perch contains 30¼ square yards. Thus:—

Acre.		Rood.		Perch.		Square yards.	Side of equivalent squares in yards.
1	=	4	=	160	=	4840	69.5701
		1	=	40	=	1210	34.7851
				1	=	30¼	5.5

The Irish acre is larger than the English, 121 Irish acres being very nearly equivalent to 196 English acres. The Scottish acre is also larger than the English, 48 Scottish acres being equal to 61 English acres. The English statute acre is used in the United States of North America.

The *Arpent* is the French square measure which most nearly corresponds with the English acre, an arpent containing 4028.9 square yards.

ACTINO'METER is an instrument employed for the purpose of ascertaining the intensity of heat in the direct rays of the sun. It consists of a hollow cylinder of glass, containing a blue solution of sulphate of copper, with apparatus for measuring the expansion of the liquid under the influence of the sun's heat. In the hands of its inventor, Sir J. Herschel, this instrument has proved highly useful in determining the quantity of solar heat which is absorbed in passing through different strata of the atmosphere. It may also be employed to determine the diminution of heat which takes place during eclipses of the sun. It has not yet been employed in the arts; but when we consider the remarkable phenomena of Photography, it will appear very probable that the Actinometer is destined to take part in many delicate chemical operations.

A'DAMANT, a word now seldom employed as a scientific term, but used chiefly as a poetical expression synonymous with diamond, or as descriptive of some other extremely hard substance. In 1849 M. Dufresnoy exhibited before the Paris Academy of Sciences, a few pieces of adamant so extremely hard, as to be able to polish the diamond. They were considered to bear the same relation to diamond, which emery does to corundum. They were met with in the same alluvial formation whence Brazilian diamonds are usually procured. The largest piece obtained weighed about 66 grains. Its edges were rounded by long-continued friction; and it presented a slightly brownish dull black colour. When viewed with a microscope, it appeared riddled with small cavities, which separated very small irregular laminæ, slightly translucent and iridescent. It cut glass readily, and scratched quartz and topaz. Its density was rather more than three times that of water, about the same as that of the diamond. The smaller specimens retained their aspect, hardness, and weight, after long calcination at a bright red heat in a covered crucible. On analysis, it was found that this adamant contains from 96.8 to 99.8 per cent of pure carbon: the small remainder consisting of vegetable ash.

ADAMANTINE SPAR is one of the many varieties of Corundum or Emery, from which it differs much in quality, but little in composition. [CORUNDUM.]

ADELAIDE, is becoming a commercial city of much importance. It is the capital of the Colony of South Australia, and is built on the river Torrens. Port Adelaide, at the mouth of the river, seven miles distant from the town, is a fine and capacious harbour, well situated in respect to the prevailing winds. At the present time (1850) a railway is being formed from Adelaide to Port Adelaide. Nearly 14,000 emigrants landed at Adelaide in the four years 1844-7, and the number has since still more largely increased.

The discovery of no fewer than seventy rich copper mines in South Australia is tending to make Adelaide an important place of shipment; while the wool-trade is also advancing with great rapidity. Adelaide was, in 1845, made a free port to the ships of all nations. The imports in the year ending April 1849, were valued at 471,556*l.*, and the exports at 485,951*l.*; 112,338 tons of shipping entered inward and outward; 16,000 tons of copper ore, and 19,000 cwt. of wool, were exported.

ADEN, a town and harbour on the southern shores of Arabia, in the province of Yemen. Before the British took possession of it, Aden was an ill-supplied miserable place, consisting of a small number of mud huts covered with mats, and containing about 600 inhabitants. At present it is a flourishing place of trade, containing from 20,000 to 25,000 inhabitants, surrounded with gardens and orchards, in which all the necessaries of life may be had at a moderate price. The British took possession of Aden in 1840, when a steam-boat navigation was established between Bombay and Suez, for which Aden serves as a central depôt. There are about a dozen steam-vessels engaged on this mail route; and if the present discussions (1850) concerning the Australian mail should result in the Singapore route being chosen, Aden will become a still more important place. Since the occupation of Aden by the British, its trade with the surrounding countries has increased, and a number of Banians, Parsees, and other merchants have settled there. It is expected that the whole commerce of the Red Sea, and especially that of Yemen and Hadramaut will soon be transferred to Aden. The exports of British manufactures thither in 1849 amounted to 14,564*l.*

ADHESION, is the property by which two solids, a solid and a fluid, two solids and an interposed fluid, or two fluids, remain attached to each other when their surfaces are brought into contact. It is a property of much importance in machinery, since *friction* depends upon it to a considerable extent. M. Guyton de Morveau found by direct experiments, that when the surfaces of plates of different metals were placed in contact with the surface of mercury, the weights required to separate them from the fluid were as stated in the following table (the metals were pure, the plates circular, one inch diameter, and of equal thicknesses):—

	Grains.		Grains.
Gold . . .	446	Zinc . . .	204
Silver . . .	429	Copper . .	142
Tin . . .	418	Antimony .	126
Lead . . .	397	Iron . . .	115
Bismuth . .	372	Cobalt . .	8
Platina . .	282		

Mr. Bevan has given a table of the adhesion, &c. of different kinds of nails when driven into dry Christiana deal; in this table it appears that a sixpenny nail, 73 to the lb., 2½ inches long, forced 1½ inches into the wood, required 327 lbs. weight to extract it; the percussive force required to drive the sixpenny nail to the depth of one inch and a-half into the dry deal, with a cast-iron weight of 6·275 lbs., was four blows or strokes falling freely, the space of 12 inches, and the steady pressure to produce the same effect was 400 lbs. With different kinds of timber the results varied greatly, and Mr. Bevan concludes that a sixpenny nail driven two inches into dry oak, would require a force of more than half a ton to extract it by steady pressure. Mr. Bevan has also determined the force required to draw screws out of different kinds of wood; the screws used were about two inches in length, .22 diameter at the exterior of the threads, .15 diameter at the bottom, the depth of the worm or thread being .035, and the number of threads in one inch 12. These screws were passed *through* pieces of wood, exactly half an inch in thickness, and drawn out from the following dry woods by the annexed weights: beech 460 lbs., another specimen 790 lbs., ash 790 lbs., oak 760 lbs., mahogany 770 lbs., elm 655 lbs., sycamore 830 lbs. The force required to draw similar screws out of deal and the softer woods, was about half the above.

ADIPOCIRE, a substance of a peculiar nature, being intermediate between fat and wax, and bearing a close resemblance to spermaceti. In 1786, Fourcroy had the opportunity of observing an accumulation of adipocire on a scale of prodigious extent, under circumstances of a peculiar nature, which are highly curious. There was in Paris an immense burial-ground, called La Cimetière des Innocens. This place had been the receptacle of the dead for a considerable part of the population of Paris for several centuries. On account of some improvements in the neighbourhood it was determined to remove this cemetery. The number of burials in this place had amounted to some thousands annually. The bodies were deposited in pits or trenches about thirty feet deep; each pit was capable of holding from twelve to fifteen thousand bodies; and as the pits became full they were covered with a few feet of earth. The extent of the whole area was about seven thousand square yards, and this space became at last occupied by a mass which consisted almost entirely of animal matter, rising several feet above the general level of the soil. Scientific men were especially charged by the government to direct the precautions requisite for securing the health of the workmen in removing this immense mass of putrefying animal matter. When the bodies were exposed to the light of day, the linen which had covered them was slightly adherent to the bodies; beneath the linen was found nothing but irregular masses of a soft ductile matter of a gray-white colour, resembling common white cheese, the resemblance being more striking from the prints which the threads of the linen had made upon its surface. The bones, which were surrounded by this matter, had no solidity, but were readily broken by sudden pressure. The head was environed with this peculiar matter; the face was no longer distinguishable; the mouth was disorganized; no trace remained of the viscera of the thorax and abdomen, which were all confused together, and converted into this fatty matter; and this was also invariably the case with the brain. None of this matter was found in bodies isolated from each other, but only in those accumulated in the common graves. From various observations it was found that this fatty matter was capable of enduring in these burying-places for thirty or forty years, but that ultimately it became corrupted and was dissipated.

The substance thus presented for examination under such remarkable circumstances, is considered by M. Fourcroy as an ammoniacal soap, formed of a peculiar oil combined with ammonia. It melts at about 130° Fahr.; by a strong heat it is decomposed with the solution of ammonia. There would of course be something repugnant in using such materials in manufactures; but French and German chemists have made attempts to convert the dead bodies of cattle into adipocire, for candle and soap-making. It is, however, found that adipocire proceeds solely from the pre-existing fat of the dead body, and not from the flesh and cartileges; and the attempts to produce adipocire artificially have not been commercially successful.

ADIPOSE SUBSTANCE, or fat, is an animal oil, which resembles, in its essential properties, the vegetable oils. It is wholly inorganic, though contained in an organized tissue. It varies in its consistence, or rather in the temperature at which it becomes solid. In general, it forms a pretty firm solid, constituting suet, which, when divested of the membrane in which it is contained, is called tallow; but there are animals in which, at the ordinary temperature of the atmosphere, it always remains fluid, as in the cetacea. At the temperature of the human body, it is fluid. It consists of two substances which are capable of being separated from each other, and obtained in a distinct form. Of these substances, one, at the ordinary temperature of the atmosphere, is solid; the other fluid. *Stearine*, the solid portion of fat, is a substance colourless, tasteless, nearly inodorous, soluble in alcohol, separable from this solution in the form of small silky needles, and preserving its solidity at a temperature of 99° Fahrenheit. *Elaïne*, the oily principle of fat, is fluid at the temperature of 60° Fahrenheit; it is of a yellow colour, without odour, lighter than water, its specific gravity being 0.913, and easily soluble in alcohol. Fat is the chief ingredient in several important manufactures, especially CANDLES and SOAP; to which articles, and to TALLOW, it may suffice here to refer.

ADIT, or DRIFT, is the horizontal passage which gives entrance to some mines. [MINING.]

ADJUTAGE, or AJUTAGE, is a name given to a tube, generally not exceeding a few inches in length, which may be applied to a vessel or reservoir, in order to facilitate the discharge of a fluid from such vessel.

ADRIANO'PLE, the second city in European Turkey, is in the province of Romania or Rumelia, 135 miles N. W. of Constantinople. An aqueduct supplies the baths, mosques, and fountains with water. The manufactures of Adrianople are silk, woollen, and cotton stuffs; it has also establishments for dyeing, and distilling rose-water and other perfumes.

ADRIATIC SEA, sometimes called the *Gulf of Venice*, is a large bay of the Mediterranean, between Italy and Turkey. The navigation is easy and safe, the numerous islands on the Dalmatian coast affording excellent shelter in the most violent gales. It has recently become one of the great lines of communication between India and Western Europe, by the route through Egypt, steam-vessels passing from Alexandria to Trieste. It is near the mouth of the Adriatic, that the two small Greek islands are situated, which formed a disputed point in the momentous Greek question of 1850.

ADULTERATION, is the use of ingredients in the production of any article which are cheaper and not so good, or which are not considered so desirable by the consumer, as other or genuine ingredients for which they are substituted. The law does not generally consider adulteration as an offence, but relies apparently on an evil of this nature being corrected by the discrimination and good sense of the public. Any one acquainted with modern shop-keeping, however, especially on the 'cheap' system, has good cause to know and to lament the difficulty of detecting such nefarious practices. The *morals* of trade are sadly neglected by many who would spurn a charge of direct dishonesty. In Paris, malpractices connected with the adulteration of food are investigated by the Conseil de Salubrité, acting under the authority of the prefect of police. In this country, also, whenever the interests of the revenue are concerned, strict regulations have been resorted to in order to prevent adulteration. Tobacco, beer, drugs, tea, coffee, cocoa, pepper, and bread, are all more or less protected against adulteration, so far as legislation can do it; but with very little real effect.

ADVERTISEMENT. In the English, Scotch, and Irish newspapers, and other periodical works, there are annually published above two millions of announcements known by the name Advertisement. The duty on a single advertisement was formerly 3*s* 6*d*. in Great Britain, and 2*s*. 6*d*. in Ireland; but by 3 & 4 Wm. IV., c. 23, it was reduced to 1*s*. 6*d*. in Great Britain, and 1*s*. in Ireland. In the year previous to this reduction the total number of newspaper advertisements published in the United Kingdom was 1021,943; namely, 787,649 in England, 108,914 in Scotland, and 125,380 in Ireland. The duty amounted to 172,570*l*., and had been stationary for several years. In 1841 the number of advertisements had increased to 1,778,957; namely 1,386,625 for England and Wales, 188,189 in Scotland, and 204,143 in Ireland. The total amount of duty was 128,318*l*.; and it has progressively increased from the time when the reduction took place. In 1849, the total number of advertisements was 2,109,179, of which 1,668,156 were for England and Wales; 234,166 for Scotland; and 206,857 for Ireland. In the last session of parliament, a considerable effort was made to induce the government to surrender this tax upon the publicity of all those announcements which arise out of a highly complicated state of society. The continual increase of advertisements, even under the tax, is a proof of the absolute necessity which exists, of supplying the public with information through this medium. No other mode of publishing is so effectual as the Newspaper Advertisements; and thus the size of newspapers has been doubled in many instances, to allow of the insertion of a greater number. Advertisements generally supply the fund out of which newspapers are supported, as the price at which the newspaper is sold is insufficient to pay the cost of the stamp, the paper, the printing, and the editorial management. The lowest price of an advertisement in a London daily newspaper is now 5*s*. (except applications for places by servants, which, in the last page of the 'Times,' are 3*s*. 6*d*.), which includes the duty: such advertisement must not exceed five lines. The usual practice is to charge 6*d*. per line for each line above four; but when the number of lines exceeds about twenty, the rate of charge is increased, the longest advertisements being charged at the highest rate. The duty on short advertisements constitutes a tax of 66 per cent. If the duty were abolished, the minimum price of advertisements would probably be 1*s*. in all but a few papers. The yearly number of advertisements in the United States, where no duty on them exists, is said to exceed 10,000,000.

ÆGI'NA, a small island in the Gulf of Ægina, forming a part of the modern kingdom of Greece. It is famed for the temple of Jupiter Panhellenius, or the Panhellénium, one of the most celebrated among specimens of classical architecture. This temple was of the Greek Doric style. It had a portico of six columns at each end, and ranges of twelve columns along each side. Internally it was divided into what may be termed nave and aisles, by two ranges of columns, the space between which was uncovered. The cell or body of the temple was a regular parallelogram inclosed by four walls: access was given to the interior by doors in the cross-walls, from inner porticoes formed by the longitudinal extension of the flank walls. The columns of the peristyle on the sides stand nearly as far from the walls as they do from each other; and a kind of gallery was formed on the floor of the peristyle around the body of the temple, raised by three deep steps from a nearly level platform called a períbolus, in the midst of which the temple stood. The extreme length of the temple in front, measured on the face of the lowest step of the regular stylobate, is 49 feet 10.2 inches, and in flank 100 feet 7·7 inches; and on the floor of the peristyle, that is, at the edge of the upper step on which the columns rest, the corresponding dimensions are, 45 feet 2·2 inches, and 96 feet. Both the tympana were highly enriched with sculptures.

The architecture of the Panhellenium indicates an earlier date than that of the Athenian temples of the age of Pericles; but it would hardly lead us so far back as the early part of the sixth century before Christ; though it is not at all inconsistent with that period. This beautiful temple is now a complete ruin. All the walls are levelled to the ground, and only some of the columns and entablatures remain. Yet it is noble, even in its ruin.

The sculptures which occupied the tympana of the pediments of the Panhellenium were discovered in May, 1811, by a party of English and German travellers, among whom were Messrs. J. Foster, of Liverpool, and C. R. Cockerell, of London, who were pursuing their studies as architects. They were found buried under the ruins of the building and accumulations of rubbish, nearly as they had fallen from their places, especially those of the western front, the whole of which were recovered; but unfortunately not more than half of those of the eastern front could be determined. Thorwaldsen was engaged to repair and restore all the statues which were not so completely broken as to render reparation impossible. Restorations of the two pediments of the Panhellenium, with casts and imitations of the figures on the tympana, have been added to the Athenian and Phigaleian marbles in the British Museum; they occupy the upper part of the north and south sides of the Phigaleian saloon, adjoining the Elgin saloon.

ÆO'LIAN HARP, a musical instrument, the sounds of which are drawn from it by a current of air acting on the strings. One may be constructed as follows:—Let a box be made of thin deal, of a length exactly answering to the window in which it is intended to be placed, four or five inches in depth, and five or six in width. Glue on it, at the extremities of the top, two pieces of oak, about half an inch high and a quarter of an inch thick, to serve as bridges for the strings; and withinside, at each end, glue two pieces of beech about an inch square, and of length equal to the width of the box which is to hold the pegs. Into one of these bridges fix as many pegs, such as are used in a pianoforte, though not so large, as there are to be strings; and into the other, fasten as many small brass pins, to which attach one end of the strings. Then string the instrument with small catgut, or *first* fiddle-strings, fixing one end of them, and twisting the other round the opposite peg. These strings, which should not be drawn tight, must be tuned in unison. To procure a proper passage for the wind, a thin board, supported by four pegs, is placed over the strings, at about three inches distance from the sounding-board. The instrument must be exposed to the wind at a window partly open; and to increase the force of the current of air, either the door of the room, or an opposite window, should be opened. When the wind blows, the strings begin to sound in unison: but as the force of the current increases, the sound changes into a pleasing admixture of all the notes of the diatonic scale, ascending and descending, and these often unite in the most delightful harmonic combinations.

ÆOLI'NA, a very small musical instrument, consisting of a number of short elastic metallic springs, fixed in a frame, and acted on by the breath of the performer. The best of the kind comprise three octaves of the diatonic sounds, and are also capable of giving the three simple harmonies of the key.

AERATED WATERS. Dr. Venables, in a recent work on aerated waters, describes the operation of Bakewell's patent apparatus, and the composition necessary for the production of different varieties of these liquids. The aeration is not confined to mere cooling drinks such as soda water, but is applicable to all cases where water is to have an effervescing quality given to it, whether for aperient, tonic, diuretic, antacid, lithotriptic, or pectic purposes. The principal feature of the process is the forced combination of a gas with pure water; and in the case of soda-water this gas is the result of chemical action between sulphuric acid and carbonate of soda.

Bakewell's apparatus consists of an upright vessel supported on a stand, and furnished with pipes and valves. In the lower part of the apparatus is a vessel called the generator, divided into two compartments by a horizontal partition. Sulphuric acid is placed in the uppermost of these compartments, and the carbonate of soda in the lower; and while the vessel is at rest, the two substances are kept wholly separate; but when a working motion is given to it by making it oscillate on two pivots whereby it is suspended, the acid drops at regular intervals through a hole in the side of the upper compartment, and falls into the lower one, where it mixes with the carbonate. A chemical interchange immediately takes place; the soda leaves the carbonic acid and combines with the sulphuric; so that instead of sulphuric acid and carbonate of soda we have carbonic acid and sulphate of soda. The carbonic acid assumes the gaseous form, and ascends to an earthenware vessel in the upper part of the apparatus. This vessel contains water; and as the apparatus is kept oscillating, the water is sufficiently agitated to absorb the gas passed up into it. With a small apparatus capable of holding a gallon at a time, a quarter of an hour's oscillation will suffice to impregnate the water with gas to a pressure of five atmospheres. The apparatus must of course be strong to resist this pressure; it is made of iron, and there is a pressure guage at the top, to measure the amount of the pressure. There is a tap for draining off the aerated liquids. Dr. Venables states that for a gallon of water to be impregnated to the extent of five atmospheres, would require about six ounces of carbonate (or rather sesqui-carbonate) of soda and four ounces of sulphuric acid. The apparatus admits of being used in many ways; for the aerator or upper vessel may be either filled with pure water, and modified only by the gas which ascends from the generator; or the water may previously be made acid or alkaline, and receive a further change by the aeration. The resulting beverage will thus depend, not only on the aeration, but also on the state of the water before aeration.

Messrs. Knight patented an air-tight stopper, in 1844, for flasks intended to contain the aerated water, when required to keep it some time for further operations; or to transfer it to the common glass-bottles. It is an ingenious piece of apparatus, strong enough to resist the expansive force of the gas, yet easily adjusted for the entrance or exit of liquids.

AERIAL BRIDGE. [BRIDGE.]

AERIAL WHEELS. This name has been given to a new form of wheel, in which the tire is made hollow and very light. [WHEEL.]

AERO-DYNAMICS signifies the science which treats of the motion of the air, or of the mechanical effects of air put in motion. There are not many points in which this science bears directly on manufacturing operations or the arts generally; but we may present a few considerations to shew its influence on moving machinery.

As soon as we begin to move we feel, more or less, the resistance of the air. And, since any body in moving through a fluid, as air, not only displaces a greater number of particles of the fluid in equal times, in proportion as it moves faster, but causes each particle to react against the body more powerfully in proportion as the latter, by moving faster, strikes it with greater force; it follows that the resistance of a fluid at rest against a body moving in it, or the resistance of the fluid in motion against a body at rest, varies with the square of the velocity of the body, or of the air; that is, if the velocity be suddenly made ten times as great, the resistance is made ten times ten, or a hundred times as great. And this is sufficiently near the truth for practical purposes when the velocities are eight or nine hundred feet in a second.

The resistance is nearly in the same proportion as the surface exposed, but a little greater than this proportion on the larger surface; that is, if we take two bodies of the same figure and material (two iron spheres for example), the surface of the second being twice that of the first, the resistance to the larger sphere is a little more than twice that to the smaller, the velocities being the same in both.

The round ends and sharp ends of solids suffer less resistance than the flat ends of the same. Thus, the sharp end or vertex of a cone is less resisted than the flat end or base.

Two solids, similarly formed on the end towards the air, are not equally resisted unless the hinder parts are also similar.

If we suppose both the wind and the body to be in motion, the resistance is variously modified according to the direction of the motions of the two. If the wind and the body move in the same direction, with the same velocity, there is no resistance, for no air is displaced by the body. If the wind move 50 feet per second, and the body 100 feet, the pressure on the body is the same as if it were at rest, with a *contrary* wind of 50 feet per second blowing on it. If the wind and the body move in contrary directions, with velocities of 100 feet, the resistance is that of a wind of 200 feet per second; and so on.

The following table shows in pounds avoirdupois, the pressure which different winds will exert upon a square foot of surface exposed directly against them. The first column is a rough representation of the second.

Velocity of Wind. Miles per hour.	Feet per second.	Force on the square foot in pounds avoirdupois	Character of the wind.
1	1·47	·005	Hardly perceptible.
2	2·93	·020	Just perceptible
3	4·40	·044	
4	5·87	·079	Gentle pleasant wind.
5	7·33	·123	
10	14·67	·492	Pleasant brisk gale.
15	22·00	1·107	
20	29·34	1·968	Very brisk
25	36·67	3·075	
30	44·01	4·429	High wind.
35	51·34	6·027	
40	58·68	7·873	Very high.
45	66·01	9·963	
50	73·35	12·300	Storm or tempest.
60	88·02	17·715	Great storm.
80	117·36	31·490	Hurricane.
100	146·70	49·200	Destructive hurricane.

A few illustrations of the resistance and pressure of the air will be met with under AIR-GUN, BELLOWS, BLOWING MACHINE, SAILS, WINDMILL, &c.

AEROLITES, or AIR-STONES, are masses of mineral substances which fall to the earth from the higher regions. As they do not bear very closely on the subject of the present work, a few details concerning them, under the heading METEORIC STONES, will suffice.

AERONAUTICS, AEROSTATICS, AEROSTATION. The first of these three words is compounded of two Greek words, which signify literally the science or art of *sailing in air;* while the other two signify the *standing of bodies in air.* The BALLOON, to which article we refer, is the most interesting machine to which these studies relate.

Æ'SCULUS, or the *Horse-Chestnut*, is a genus of plants which subserves a few useful purposes. The popular name of *horse*-chestnut has arisen from the custom among the Turks of grinding the nuts, and mixing them with the provender given to horses that are broken-winded. Starch is yielded in very considerable quantity by the nuts; but they are not used in the preparation of the starch of commerce. They contain, moreover, so large a quantity of potash as to be a useful substitute for soap; on the latter account they were formerly employed extensively in the process of bleaching yarn, but are now seldom used. The bark, which contains a great deal of tannin, is not a bad substitute for Peruvian bark in fevers; and, finally, the starch of the nuts, deprived of its bitterness by maceration in weak ley, has been recommended as excellent and nutritious food for horses, goats, oxen, and sheep. The timber is soft and spongy, and of little value.

ÆSTHE'TICS. *Æsthetik* is the designation given by German writers to a branch of philosophical inquiry, the object of which is a philosophical theory of the beautiful, or, more definitely expressed, a philosophy of poetry and the fine arts, and which has by them been raised to the rank of a separate science. The word *Æsthetik* is derived from the Greek (that which concerns feeling or perception), and was first used as a scientific term by Alexander Baumgarten, a disciple of Christian Wolf, who in his *Æsthetica* (Frankfort, 1750-58), considered beauty as a given property of objects, of which we are *becoming sensible*. Winckelmann, without embodying his views in a regular system, developed them chiefly in reviewing and appreciating the remains of antient sculpture. Kant denied the possibility of a strict science of beauty, inasmuch as beauty, according to him, is not a property of objects, but has its origin in the disposition of our mental faculties. Beauty, according to Schelling, is that manifestation of the principle of art where the infinite appears contained in, or represented by, the finite, or where, in the very object, the difference between the conscious and the unconscious (mind and nature) is annulled.

Most German writers who have published systematic treatises on æsthetics, have, with greater or less independence, followed the principles laid down by Baumgarten, Kant, or Schelling. They commonly divide their systems into a general part, or a discussion of the essence of beauty and art, and a special one, or an inquiry into the peculiar character and predominant principles of the several branches of poetry on the one hand, and the fine arts (chiefly sculpture, architecture, painting, and music) on the other.

In England it is not customary to write formally on Æsthetics as a science; but the principle of beauty in art has been discussed by Alison, Payne Knight, Burke, Price, Lauder, Reynolds, Bell, Dugald Stewart, Jeffrey, Hay, Ruskin, Fergusson, and others — who have, however, failed to arrive at anything conclusive and generally accepted; for there are few subjects on which opinions are more discordant than on this.

ÆTHER (*αἰθήρ*), a Greek word, now used to signify a highly volatile, penetrating, and combustible fluid, several kinds of which may be produced by the action of different acids upon spirit of wine, or alcohol. Sulphuric, phosphoric, arsenic, fluoboric, chloric, muriatic, nitric, silicic, acetic, benzoic, citric, gallic, oxalic, and tartaric acids—all yield æther by particular modes of treatment.

Sulphuric æther, obtained by distillation from a heated mixture of alcohol and sulphuric acid, is the chief kind. It is a colourless transparent liquid, of a pleasant smell and a pungent taste, extremely exhilarating, producing a degree of intoxication when its vapour is inhaled by the nostrils. Its specific gravity is from .700 to .750. It evaporates so rapidly that if we put some into a small glass vessel surrounded with cloth and containing water, and after dipping it two or three times into æther, allow the æther after each immersion to evaporate, the water in the glass freezes by the cold produced. In the open air æther boils at 96°, and in a vacuum at 20° below zero. In the open air it remains unfrozen at 60° below zero. Its vapour is nearly three times as dense as common air. It combines sparingly with water, but with alcohol in all proportions. Both æther, and the vapour which rises from it, are very inflammable. The resins and most of the oils are dissolved by æther; it dissolves a small portion of sulphur and of phosphorus, and the latter solution becomes luminous in a dark room, when poured on the hands or on hot water. The alkalies, potash and soda, are insoluble in æther.

Most of the other æthers possess properties analogous to those of sulphuric æther. Acetic æther is used for flavouring British brandy.

Æthers present the most perfect examples of volatile stimulants, being unequalled for rapidity of action when immediate aid must be imparted to the muscular system, especially the involuntary muscles, by augmenting the nervous power, and by quickening its development. Sulphuric æther is the most powerful of æthereal preparations, and therefore of diffusable stimulants. It ranks as an antispasmodic of the highest kind. The vapour of æther has been lately employed for the purpose of producing insensibility, during which the most painful operations in surgery have been performed without being felt by the patient. Teeth have been extracted in this state, both in this country and America; and several capital operations have been performed without pain to the patient. It would have been extensively employed in this way, had not *chloroform* been discovered to be a still more effective agent. Æther is usefully employed in many chemical and manufacturing processes.

ÆTNA, a celebrated volcanic mountain in Sicily is noticeable in a commercial point of view for its supplies of pumice and snow. The pumice-stone, that light porous substance which is so useful in many processes of grinding and polishing, is the lava of Ætna and Vesuvius and similar volcanos, where it is found in exhaustless quantities. In many parts of Ætna, strata of lava have been formed 300 feet thick.

For more than half the year the upper part of the mountain is covered with snow; and it forms the great store from which Sicily and Malta are supplied in summer with that necessary of life in a hot climate. After the hot summer of 1828 a search was made for an additional supply of snow; and this elicited the curious fact, that a glacier or field of ice had been prevented, perhaps for ages, from melting, by being covered with a stream of lava. Mr. Lyell supposes that this ice was formed from a mass of drift snow, which was afterwards covered by an enormous thickness of lava, the heat of which was kept from the snow by an intervening layer of volcanic sand.

AFFINITY is a term used to express the tendency of different substances to unite chemically. The expressions chemical affinity and chemical attraction are applied indifferently to that power by which bodies combine and form compounds always possessing some properties very different from those of their constituents, and frequently diametrically opposite to them. It differs from the attraction of gravitation in not acting on masses, and only at sensible distances. In this last property it resembles cohesive affinity, but is distinguished from it by occurring only between the particles of dissimilar bodies. Thus, the particles of a mass of sulphur are held together by *cohesive* affinity, and so also are those of a mass of copper; but if a particle of sulphur be brought into contact with a particle of copper (under a particular application of heat), the two particles being different, and possessing *chemical* affinity for each other, unite by this power, and form sulphuret of copper.

In all mere *mixtures*, such as alcohol and water, or salt and water, the two may act together in almost any proportions; but in the chemical *compounds* brought about by affinity, the proportions are always definite. Some liquids, such as mercury, water, and oil, have no tendency to unite in any proportion whatever, unless by indirect means.

The simplest cases of chemical affinity are those in which two bodies unite into a binary compound. This is the result of what is termed *single affinity*, and this power may be exerted between two elementary or two compound bodies; and also, though it occurs more rarely, between an elementary and a compound substance. Sulphur and copper for example, both elementary bodies, readily unite when heated; and sulphuric acid and oxide of copper, both compounds, combine with great readiness.

The effects of chemical combination, thus induced, are very remarkable. For instance, sulphur is yellow and copper is red, but a compound of the two is black. Acids give a red tint to vegetable blues, and alkalies give them a green tint; but a salt compounded of an acid and an alkali seldom affects the colour. There are numerous other cases in which the form, colour, smell, taste, density, and other physical qualities, and the chemical properties of fusibility, volatility, solubility, and tendency to combination, in the compound, bear no resemblance to those of its constituent parts.

The force with which bodies chemically unite arises from mutual and equal affinity: thus, sulphuric acid and potash combine, not merely on account of the affinity of the acid for the alkali, but of the alkali equally for the acid. Each substance, too, has a power of unity with many others; and as this power or tendency is stronger in some instances than in others, there exists what is termed *elective affinity*, or a sort of preference (so to speak) in the combining action. An example will illustrate this;—Nitric acid is capable of combining by *single affinity* with lime or with magnesia; and if some dilute nitric acid, containing 54 parts of real acid, be mixed with 28 parts of lime, the earth will be dissolved in the acid, and a neutral solution of nitrate of lime is obtained. A similar quantity of this acid forms a neutral solution of nitrate of magnesia by combining with 20 parts of that earth. Now, if we mix together 54 parts of nitric acid, 28 of lime, and 20 of magnesia, it might be supposed that the acid—which is of course incapable of dissolving the whole of both of the earths—would dissolve them in the proportions of 14 of lime and 10 of magnesia: it is found, however, that this is not the case, for the whole of the lime is dissolved, and the magnesia entirely left. This arises from the nitric acid having an *elective affinity* for lime rather than for magnesia.

To exhibit the degrees of elective affinity, tables are constructed, in which the substance whose affinities are to be expressed is placed at the head of a column, and is separated from the rest by a horizontal line; beneath this line are arranged the bodies with which it is capable of uniting, in the order of their respective forces of affinity; the substance which it attracts most strongly being placed nearest to it, while that for which it has the least affinity is placed at the bottom of the column. Such a table is useful, but not always accurate.

Another variety is that of *double elective affinity*, in which two compounds mutually decompose each other. Thus, sulphuric acid, carbonic acid, strontia, and potash, are so characterised with respect to mutual affinities, that if sulphate of strontia and carbonate of potash be made to act on each other, both are decomposed, and the components re-unite to form sulphate of potash and carbonate of strontia.

Chemical affinity works much more powerfully when the bodies are in the liquid than the solid state, in most cases; while others, again, require the gaseous state for its full development.

Proportion, *heat*, *electricity*, and *light*, all influence the strength and nature of affinitive combination. If sulphuric acid and alcohol be combined in the ratio of equality, they produce sulphuric æther; but if the proportion of acid be ten times as much as that of alcohol, olefiant gas is produced. With respect to *heat*, the difference is not less striking. If we mix oxygen and hydrogen gases, they will remain in a state of mixture for an indefinite period without combining; but if flame be applied to them they combine with explosion, and water is formed. Water dissolves certain salts, but to a limited extent only when cold; boil it, and the solvent power is greatly increased. When mercury is moderately heated in atmospheric air it is converted into peroxide, by combining with the oxygen of the air: heat the compound thus formed more strongly than was required for its production, and the affinity is destroyed: oxygen gas is given out, and the mercury returns to its metallic state. And so on of other bodies.

Electricity possesses remarkable power over chemical affinity. Indeed so intimate is the connection between the two, that it is now known that no chemical action takes place without electric action being also manifested. This part of the subject, developed as it has been by professors Faraday and Daniell, is noticed under ELECTRO-CHEMISTRY. In the mean time the following will serve as an example of the reversal of chemical affinity by electricity. Immerse a piece of copper in a solution of nitrate of silver, the copper is dissolved and the silver precipitated; if we reverse the experiment, and put a piece of silver into a solution of nitrate of copper, no change is effected; if, however, the silver while immersed be touched by a piece of iron, the order of affinity is reversed, the copper is precipitated, and the silver is dissolved.

Light is capable of controlling chemical affinity, both with respect to decomposition and combination. If a mixture of hydrogen and chlorine gases be exposed to the sun's rays, they combine with explosion, and form muriatic acid: this effect does not appear to be produced by the heat which accompanies the light, for a considerably higher temperature is not capable of producing the combination. Or if pale nitric acid be subjected to the action of light, it suffers decomposition to a certain extent, oxygen gas being evolved.

Chemical affinity has a most important influence on many branches of manufacture. Bleaching, dyeing, and calico-printing depend wholly on it; as these processes are guided by relative powers of combination in different substances. All metallurgic processes in which mixed metals are concerned, such as steel, brass, pewter, bronze, &c.; and nearly all operations in which heat or solution are employed—are in like manner dependent on the affinities of different substances one for another.

AFGHANISTAN, or the country of the Afghans, comprehends a large district between India and Persia, lying between 28° and 35° N. lat., and between 62° and 73° E. long. The valley of Kabool contains many fertile and beautiful spots, studded with villages. The dried fruits of Kabool constitute the principal article of trade; they go to Hindustan. Grapes of a dozen different kinds are grown, but only two species bear exportation. Red and white melons are raised in abundance. The wild rhubarb root is used to make preserves; and the vegetables are excellent. On the slope of the Suliman mountains at the eastern part of Afghanistan, is the Salt-range, where extensive beds of rock-salt are found interstratified with limestone.

The central table-land of Afghanistan being very arid, the natives adopt an ingenious mode of forming aqueducts for irrigation, by which the water of a hill or rising ground is brought out at its foot in a rivulet, to be disposed of at the pleasure of the farmer. Such aqueducts, called *karezees*, are made in the following manner. A well is made at the spot where it is intended the water shall issue; above it in the acclivity is dug another at the distance of five to twenty yards, according to circumstances. The wells are continued at distances generally equal, until the quantity of water collected in them is deemed sufficient, or until the depth of the wells becomes so great that the expense exceeds the advantage. If the acclivity is not very gentle, the highest wells must be very deep, as their bottom must be only slightly elevated above the level of the water in the lower wells. All these wells are then connected by means of aqueducts made under the surface of the ground, through which the water from all of them flows to the foot of the hill.

Afghanistan has great mineral wealth. Gold, silver, and copper, are found in various parts; some of the iron found near Peshawur is believed to be nearly equal to that of Sweden, and is largely exported to India. Lead, salt, alum, and saltpetre, are also among the natural products of the country.

The grains cultivated are wheat, barley, peas, beans, maize, rice, and some other grains of Hindustan, as jowary, chuna, musoor, bajra, moth, moong, oord, and murhwa. The most common vegetables are carrots, turnips, radishes, lettuce, cauliflowers, onions, garlic, melons, and cucumbers, with a few others from Hindustan. Madder is extensively grown on the central table-land; and turmeric, assafœtida, and many other useful plants, grow extensively. Forests are only found on the Himalaya mountains and the Sufaid-Coh. There are no woods on the table-land, and all the trees found there are planted generally in rows along the water courses and canals, and around the orchards. The mulberry tree is very extensively cultivated; and among the fruits grown are apples, pears, cherries, plums, apricots, peaches, quinces, and pomegranates.

The most important of the domestic animals are the sheep. There are two kinds, both with the broad fat tail, which in some parts of the Eimack mountains is so large that a small cart or frame is put under the tail to support it. These sheep yield two fleeces: the spring or coarser fleece is used for carpets, grain-bags, and other coarse stuffs; the autumn or finer fleece is manufactured into cloth, cloaks, and mummuds or rugs. Goats are nearly as numerous as sheep; and some of them yield a fine and remarkably soft down, which grows at the root of the hair: the hair is long and usually jet black, but the down is of a shade more or less intensive. Horses, mules, and asses are plentiful; camels and cattle less so. The cats of Kabool are distinguished by their long silky hair, and go under the name of Persian cats, though very few of them are found in Persia, and none are exported from that country. These cats are exported in great numbers from Kabool, where the people encourage the growth of the hair by washing it with soap and combing it.

The chief articles manufactured for export are silk, woollen stuffs, sword-blades, and fire-arms, from Herat and Candahar. Elphinstone enumerates the following as the chief industrial occupations for home produce at Candahar:—Jewellers, gold and silver smiths, booksellers, bookbinders, stationers, makers of kullumdauns (a sort of inkstand and pen-case, of which every man who can write has one), seal engravers, sellers of armour, sellers of shields (these shields are of buffalo's or rhinoceros's hide), gunsmiths, sword-cutlers, polishers of steel, sellers of bows and arrows, sellers of glass ornaments for women, three descriptions of shoemakers, bootmakers, button-makers, silk thread sellers, gold wire and gold thread sellers, saddlers, farriers, painters, fruiterers, cooks, soup-sellers, tobacconists, druggists, perfumers, sellers of sherbet and of fullodeh, confectioners, embroiderers, and people whose business is to sew ornaments on clothes of all descriptions, from jewels to spangles.

As Afghanistan has no navigable rivers, the transport of merchandise is expensive, and the expense is increased by the want of roads, which are not met with in all Western Asia, from the Indus to the Straits of Constantinople. The conveyance of merchandise is therefore effected by beasts of burden. Camels are mostly used in the level countries, and mules or asses in the mountainous districts. Nearly all the land commerce existing between India on one side, and Persia, Turkistan, and China on the other side, must be carried through Afghanistan. Of these lines of communication, the most northern goes by way of Loo-dianah, Lahore, Attock, Peshawur, to Kabool, on the way to Bokhara. A middle line leads from Lahore to the table-land, where it branches to Ghuznee and Candahar. A southern route reaches Candahar from the mouth of the Indus. From Candahar a route passes westward into Persia.

An active commerce is carried on between

Herat and Meshed and other towns in Persia. The exports from Herat consist of shawls and shawl goods, indigo, carpets of Herat, Mooltanee chintz, Indian brocades, muslin and other cotton-cloth, assafœtida, lead (from the mines of the Eimack), cast-iron, saffron, pistachio-nuts, gums, a yellow dye, carraway seeds, and paper. The imports of Herat are chiefly silk, dates, tobacco, lemon-juice, and ivory heel-taps.

Several caravans go annually from Kabool to Bokhara. They export chiefly articles which have been imported from India, especially shawls and shawl-cloth, white cloth of all kinds, India turbans, Mooltanee chintz, indigo, and spices; and they import from Bokhara principally horses, and gold and silver in coins and bars. Some articles brought from Russia are also imported by these caravans, especially cast-iron pots, cutlery and other hardware, needles, looking-glasses, Russia leather, tin, beads, and spectacles. A fine cloth made of camel's wool, some raw cotton, and some lambskins, are also brought from Bokhara and Balkh.

AFIOUM KARA HISSAR, a city and fortress situated almost in the centre of Asia Minor, about 200 miles from Smyrna, is a great trading thoroughfare; as it lies on the route leading from Smyrna to Armenia, Persia, and the countries bordering on the Euphrates, and as being the rendezvous of the caravans from Constantinople and Smyrna, which from this place proceed further into the interior. Hence nearly all European manufactures and colonial produce, which are distributed eastward and southward, pass through Afioum. This circumstance renders it a place of considerable importance and activity; and in no other town in this part of Asia Minor are the houses so well built or the shops so well supplied. Its manufactures of wool, tapestry, fire-arms, sabres, and red leather are of some importance; but its chief article of commerce is opium ('afioum'), of which a very large quantity is prepared annually. From the cultivation of opium here it derives its name, which signifies "The Black Castle of Opium." In the country between this place and Smyrna most of the Turkey carpets are made.

AFRICA. The Mediterranean coast of Africa has been known from very early times —more remote, indeed, than that of Europe; but down to so late a date as the beginning of the 15th century, the only portion of the west coast of Africa with which European navigators were acquainted was that between the Straits of Gibraltar and Cape Nun, or Nam, or Non, in 28° 40' N. lat., an extent of not much more than six hundred miles. From this latter point commenced that career of discovery, by the Portuguese, by which the entire coast of Africa has been made known to the modern world. Between the time of Prince Henry of Portugal (1415) and Vasco de Gama (1497), the Portuguese tracked the whole western coast of Africa from the Straits of Gibraltar to the Cape of Good Hope, and the whole east coast to within 1,000 miles of the mouth of the Red Sea, a distance, in all, of more than 10,000 miles.

The 16th and 17th centuries were marked by discoveries and settlements on the rivers Senegal, Gambia, and Zaire, on the west coast.

The Dutch, the Danes, the French, and the English, all made attempts to imitate the Portuguese in their African researches; but little was effected until about sixty years ago. It is since the formation of the African Association, in 1788, that the chief efforts have been made in the prosecution of discovery in the interior; and it is important for us to notice such enterprises here, for they were induced almost wholly by commercial and manufacturing considerations—the principle of interchange of commodities. The expeditions sent out by the Association and by government, and those undertaken by individual adventurers, have sought Timbuctoo and the Niger from various points. But no considerable progress was made till the first journey in 1795 and 1796 of Park, who, on that occasion, proceeding from the west coast in the direction of the Gambia, discovered much new country in the neighbourhood of Timbuctoo, and found reason to think that the Niger or Joliba (hitherto confounded with the Senegal by the Portuguese) was a wholly distinct river. On his second expedition, which was undertaken at the public expense, in 1805, this adventurous traveller succeeded in sailing a considerable way down the Niger, passing Timbuctoo and many other cities, near one of which he was murdered.

After a few partial discoveries, by Hornemann and Riley, an expedition was sent out by the government in 1816, under the command of Captain Tuckey, to the Congo, with the idea that it would be found to be the same with the Joliba or Niger; he ascended that river for about 280 miles, and also examined part of the adjacent country. At the same time Major Peddie, and after his death Captain Campbell, conducted another party from the mouth of the Senegal, through the Foulah territory, as far as Kakundy. In 1817 Mr. Bowdich explored a part of the extensive territories of the Ashantees; and soon afterwards very considerable additions were made to the knowledge formerly possessed both of the geography and the people of interior Africa, by the publication of Mr. Jackson's account of the territories of Timbuctoo and Houssa, from the communications of El Hage Abd Salam Shabeeny, a Mussulman merchant, who had visited these states.

Various discoveries were made by Mollien, Ritchie, Lyon, and Laing, who respectively started for the interior from Senegal, Tripoli, and Sierra Leone. But a more important and successful attempt than any which had been hitherto made to explore the interior of Africa was that of Major Denham and Lieutenant Clapperton, in 1822. These travellers, setting out from Tripoli, along with a caravan of Arab merchants, crossed the desert, and reached the great inland sea or lake called the Tchad. The two travellers, sometimes together, and sometimes separated, visited Bornou, the Fellatah country, and Sackatoo; but they could not trace the Niger (called at Sackatoo the Quorra) to its mouth. In a second expedition Clapperton reached Sackatoo from Guinea, and there died. His servant, Richard Lander, afterwards returned a considerable way towards the south, intending to embark on one of the branches of the Niger, and, if possible, to solve the grand problem of its termination by sailing down the stream. But he was stopped by the natives, and compelled to turn back when he had got as far as Dunrora, which he understood to be due west of Funda, and at no great distance from it. Meanwhile, Major Laing had succeeded in making his way across the desert from Tripoli to Timbuctoo, in August, 1826, and had transmitted some brief notices of that famous city, where he spent some weeks. But he was murdered on his return, in the desert, and none of his papers have yet been recovered. Timbuctoo was also reached from Sierra Leone by Caillé. The journey, however, which solved the problem of the Niger, was that of Richard and John Lander. Leaving Badagry on the 22nd of March, 1830, these two travellers, following nearly the same route which had been taken by Clapperton through the kingdom of Eyeo, reached Boussa on the 17th of June. They afterwards ascended the river as far as Yaouri, from which they returned to Boussa, where they remained for some time, and then embarked on the river, which they hoped would conduct them to the sea. In this expectation they were not disappointed. After various adventures, Richard Lander had at last the happiness, on the evening of the 18th of November, to find himself at the mouth of the greater branch of the river, here called the river Nun, in that gulf or depression known as the Bight of Biafra.

When the news of Lander's success reached England, a commercial company at Liverpool determined to send out an expedition, with a view of opening an intercourse with the centre of Africa. Mr. Lander, Mr. Macgregor Laird, and Captain Allen, were of the party; and two small iron steam vessels were provided, which it was hoped might ascend the Niger in safety. The expedition sailed in 1832; but it turned out most disastrous, being attended with a fearful loss of life. The merchants of Liverpool, however, succeeded in establishing a commerce with the natives by degrees; and in 1840 the government determined to send out an expedition; under an impression that trade and treaties with the African chiefs might lessen the horrors of the slave trade. This was also attended with much loss. Captain Becroft ascended the Niger about the same time, in a vessel sent out by Mr. Jamieson, of Liverpool. Mr. Holroyd, Mr. Oldfield, and Messrs. Moffat and Smith, all increased our store of information concerning those regions, shortly before the period just named. In 1842 Captain Allen explored new regions in western Africa. In 1841 and 1842 Dr. Beke spent a year in Abyssinia, and many researches were made by other travellers in the upper valley of the Nile. In 1843 Major Harris returned from his mission to Shoa, by which much knowledge was gained of that region. In 1844 and 1845 many travellers were exploring the northern half of Africa, in various directions: and the Journal of the Geographical Society now yearly contains the results of such expeditions.

The zeal for discovery in Africa, which has been so strongly felt within the last half century, has also sent out a succession of travellers to explore the southern regions of that vast continent. The principal settlement in this quarter, that of the Cape of Good Hope, was founded by the Dutch about 1650, and remained in their hands till it was finally taken from them by the British in 1806. For more than a hundred years after the establishment of this colony it occupied only the extreme angle of the African continent, or a part of the narrow tract between the sea and the nearest mountains; nor does much information seem to have been obtained with regard to any of the native tribes, except the nearest Hottentots lying beyond that boundary. The first traveller who penetrated any considerable way into the interior was Captain Henri Hop, who was sent out on an expedition of discovery by the Dutch governor in 1761, and traversed a considerable part of the country of the Namaquas. He was followed by Sparrman, Vaillant, Barrow, Trutter, Somerville, Cowan, Donovan, Lichtenstein, and Burchell, who, between 1775 and 1812, traversed much of the country north and east of the Cape. In 1820 and 1823 Burchell and Thompson penetrated far to the north. In 1836 and 1837 Sir J. E. Alexander explored much of the country inhabited by the Boschmans and other tribes north of the Cape of Good Hope. Since this date, exploring expeditions have been made by the missionary Krapf, Lieutenant Ruxton, Mr. Ackermann, M. Maizan, and others in various directions.

In short, it may be stated, that approaches are now being made towards the centre of Africa, from almost every side of that great continent. The recent lion-hunting, elephant-killing excursion of Mr. Gordon Cumming, can hardly be termed a geographical exploration.

The mineral treasures of this immense continent are of course very imperfectly known. Salt is perhaps one of the most universally diffused, being found from the salt lakes of the Cape colony to the northern coast. It will probably be found on inquiry that the mineral treasures of Africa are nearly as various as those of other parts of the world, though at present less perfectly known, and in many cases only observed at spots widely removed from one another. The mineral wealth of Egypt alone is considerable; and that of the interior west of the Mozambique coast is also abundant. Gold dust, however, is that which has the most excited the cupidity of Europeans; and this mineral is found in the sands of the upper streams of nearly all the great African rivers. Besides gold and salt, the chief mineral products are silver, copper, iron, tin, lead, chalk, sulphur, and a few indications of coal.

The nature of African vegetation depends greatly on the latitude. The principal objects of cultivation in the Barbary States are a kind of wheat (*Triticum durum*), the stems of which are solid, and the grain horny rather than farinaceous; barley, which the Moors give their horses instead of oats, maize, durra (*Holcus sorghum*), rice, tobacco, olives, oranges, and figs of the most delicious quality; pomegranates, grapes, and jujubes, together with sweet melons and water melons. In the districts watered by the Nile we find all the richness of vegetation of the spring months of Barbary; abundance of rice, barley, and wheat; rich fields of sugar-canes; olives, figs, vines, and plantains that have been introduced; while in the hotter or drier, or more southern districts, the date is the chief object of the scenery. In the richer parts of the country we find the acacias which produce gum arabic, large tamarisk trees, called atlé, great quantities of the senna plant (*Cassia obtusifolia* and other species), intermixed with various herbs belonging to tropical genera, all of which are either unknown or very rare in the more northern parts of Africa. Cotton, coffee, indigo, and tobacco are cultivated with the greatest success. At Thebes first begins to appear a third race of palms different from the date and the palmetto, namely, the forky-branched doom palm (*Crucifera Thebaica*) of Upper Egypt. In the equinoctial parts of Africa all trees of European vegetation, and even the date tree itself, disappear. The landscape is characterized by masses of the unwieldy baobab (*Adansonia*), the fruit of which affords the natives a grateful drink, huge cotton trees (*Bombax pentandrum*), thick groups of oil palms (*Elais Guineensis*), sago palms (*Sagus raphia*), and others of the same majestic tribe. In some places the woods abound in pine-apples; while the plains are often covered with immense quantities of the papyrus plant. Among the plants cultivated for food are the cassava, the yam, the pigeon pea, and the ground-nut; the papaw, the tamarind, and the nitta or doura tree; the Senegal custard apple, the gray plum, the Safu, and the musanga, the seeds of which are as agreeable as hazel-nuts, and many others less common. Near the Cape of Good Hope the plants partake more of a milder climate.

Among domestic quadrupeds, the horse, the ox, the buffalo, the sheep, the goat, and the camel, may be enumerated. It is in the northern and central regions that the camel and buffalo are used. Dogs are numerous, and in Mohammedan towns have no particular owners, but are tolerated for their utility.

Under the headings ABYSSINIA; BARBARY; CAPE OF GOOD HOPE; EGYPT; GAMBIA; NIGER; SAHARA; SENEGAL; TIMBUCTOO, &c., will be found details respecting the productions, manufactures, and commerce of various parts of Africa.

AFRICAN COMPANY, a regulated trading company, established by act of Parliament in 1754. In the course of time it happened that the whole expense of the Company came to be defrayed by the public, and for this reason the charter of its incorporation was recalled by Parliament in 1821. The possessions of the Company on the west coast of Africa were by this act annexed to and made dependencies upon the colony of Sierra Leone.

AFTER-MATH is the grass which grows after the hay has been made; it is also called

KNIGHTS CYCLOPÆDIA OF THE Industry of all Nations.

No. 3.

latter-math, rowen, or rowett, and when left long on the ground it is called fogg in some places. Where the land is rich and hay valuable, the after-math is often mown and made into hay. This hay is inferior in value and nourishment to the first crop, which contains the flower-stalks of the grass. It is not good for horses, especially those which are driven fast and work hard; it is thought injurious to their wind. Cows and sheep are fond of it, and with them it is not liable to the same objection.

AGA'RICUS is the botanical name by which all the species of *mushrooms*, properly so called, are collectively known. This genus consists, according to the latest writers, of not fewer than a thousand species, inhabiting meadows, heaths, rocks, and masses of decaying vegetable matter, in all parts of Europe, and in many other parts of the temperate regions of the earth. Among them a large proportion are poisonous, a few are wholesome, but by far the greater number are altogether unknown in regard to their action upon the human constitution.

Agaricus Campestris, the common mushroom, is the species that is so frequently raised artificially for food. This is readily known in any state by its fragrant odour, by which alone it may be always recognised, and the absence of which is extremely suspicious. When in a very young state, it resembles little snow-white balls, which are called *buttons;* afterwards it acquires a stalk, separates its cap, and becomes shortly conical, with liver-coloured gills, and a white, thick, fleshy cap, marked with a few particles of gray. At a more advanced age, the cap is concave, the colour gray, and the gills black; in this state it is called a *flap*. Mushrooms appear in the fields chiefly after Midsummer, in the months of July, August, and September. They are indigenous, and spring up abundantly in fields where cattle have been pastured. Much care is bestowed, in some districts, in the artificial culture of mushrooms.

Agaricus pratensis, or *oreades*, the fairy-ring mushroom, is so well known by its popular designation as to require no description. It may easily have gained that name; for, in former times, there would doubtless be great difficulty in imagining how such productions could spring up in a few hours in the regular rings they appear in, without the aid of some supernatural agency. The use to which this species is usually applied is that of being powdered and mixed with rich sauces, after having been previously strung upon a line, and dried in the shade.

AGATE, sometimes called *Scotch Pebble*, is an ornamental stone used in jewellery. It is one of the many forms under which silica presents itself, almost in a state of purity: constituting in the agate 98 per cent. of the mineral. It presents a semi-translucent mass with a sort of resinous fracture; and is sometimes tinted by a minute quantity of iron. The variations both of translucency and of tint in the same stone are often so great as to give much richness of appearance; and this combined with the high polish which they are capable of receiving, imparts great value to some specimens of agate.

These stones generally occur in the form of detached rounded nodules, in a variety of the trap rocks called Amygdaloid. The particles often arrange themselves in layers parallel to the surface; and the centre has in some specimens a hollow space containing crystals of other minerals. It is supposed that agates have been formed in a kind of lava produced by igneous or volcanic action.

There are many gems which so closely resemble the agate in chemical constitution as to render it convenient to notice them briefly in this place. *Carnelian* or *cornelian* is coloured with shades of red and yellow: the deep clear red being the rarest and most valuable. It is brought chiefly from the East Indies, and is much used for engraved seals. *Calcedony* presents generally a milky white or pale yellow colour, with very often a wavy internal structure. It is sometimes met with in the British isles, in such large masses as to be formed into cups and other vessels. *Onyx* has the particles arranged in parallel layers: white alternating with blue, gray, or brown. The onyx was much used by the ancients for cameos: the figure or device being cut out of the opaque white, and the dark part forming the ground. A Roman cameo of this kind, in the Royal Library at Paris, measures as much as 11 inches by 9. *Sardonyx* is a variety of the onyx, in which the opaque white alternates with a rich deep orange brown of considerable translucency. *Mocha Stone* is a semi-transparent calcedony, in which varied tints are produced by the presence of iron and other bodies. *Moss Agate* closely resembles Mocha stone. *Blood-Stone* is a green agate, coloured with bright red spots like drops of blood. *Chrysoprase* and *plasma* are two varieties of calcedony having a green tint.

Sir H. T. De la Beche, in his Anniversary Address to the Geological Society in 1848, drew attention to the artificial colouring of agate. The agate workers of Oberstein are in the habit of imparting colour to that substance: an art derived from the Italians. It depends on the difference of porosity in the different layers of the agate. By immersion for some time in honey and water or olive oil, so that the pores of the agate become more or less filled, a subsequent soaking of the stone in sulphuric acid produces a difference in the tints of the agate according to the porosity of the layers, the most porous becoming black, while the least porous remain white or uncoloured. By immersion in a solution of sulphate of iron, and a subsequent heating of the agate, a cornelian red is in like manner obtained in the most porous layers, while the least porous remain unchanged in colour. It is supposed that some of the agates which have come down to us from antiquity have been artificially coloured.

In the Exhibition of works of Mediæval Art, at the rooms of the Society of Arts in 1850, many exquisite specimens of agate were collected.

AGA'VE, in Botany, comprehends those plants which gardeners call American aloes. There are many species of this genus, one only of which requires to be mentioned here, viz, the *Agave Americana*, or American Aloe. This is a plant, which, when full grown, has a short cylindrical woody stem, which is terminated by hard, fleshy, spiny, sharp-pointed, bluish-green leaves, about six feet long, and altogether resembling those of the arborescent aloes. It is commonly supposed that this plant only reaches maturity at the end of one hundred years; but this, like many other popular opinions, is an error, the period at which the agave arrives at maturity varying, according to circumstances, from ten to fifty or even to seventy years. In hot or otherwise favourable climates, it grows rapidly, and soon arrives at the term of its existence; but in colder regions, or under the care of the gardener, where it is frequently impracticable to attend to all the circumstances that accelerate its development, it requires the longest period that has been assigned to it. Having acquired its full growth, it finally produces its gigantic flower-stem, after which it perishes. This stem is sometimes as much as forty feet high, and is surrounded with a multitude of branches arranged in a pyramidal form, with perfect symmetry, and having on their points clusters of greenish yellow flowers, which continue to be produced for two or three months in succession. The native country of the American aloe is the whole of America within the tropics, from the plains nearly on a level with the sea, to stations upon the mountains at an elevation of between 9,000 and 10,000 feet. The sap may be made to flow by incisions in the stem, and furnishes a fermented liquor, called by the Mexicans *Pulque;* from this an agreeable ardent spirit, called *Vino Mercal*, is distilled. The fibres of the leaves form a coarse kind of thread; the flowering stems dried make an almost imperishable thatch; an extract of the leaves is made into balls, which will produce a lather with water; the fresh leaves themselves cut into slices are occasionally given to cattle; and finally the centre of the flowering stem split longitudinally is by no means a bad substitute for a European razor strop, owing to minute particles of silica forming one of its constituents.

AGE OF TREES. The immense consumption of timber in the manufactures of this and many other countries, renders it interesting to note the circumstances which distinguish different kinds of trees, in respect to duration and growth.

Besides annual and biennial plants (whose age is indicated by their names), the remainder of the more perfect part of the vegetable kingdom, whether herbaceous or shrubby or arborescent, consist of plants which may be classed under two principal modes of growth. One of these modes is to increase, when young, in diameter, rather than in length, until a certain magnitude is obtained, and then to shoot up a stem, the diameter of which is never materially altered. The addition of new matter to a trunk of this kind takes place by the insinuation of longitudinal fibres into the *inside* of the wood near the centre; on which account such trees are called *Endogenous*: they also bear the name of *Monocotyledons*. The other mode is, from the beginning, to increase simultaneously in length and diameter, but principally in length. The addition of new matter to a trunk of this kind, takes place by the insinuation of longitudinal fibres into a space beneath the bark, and on the *outside* of the wood near the circumference; on which account such trees are called *Exogenous*; they also bear the name of *Dicotyledons*.

To the first of these classes belong the palm tribe and some other tropical trees. There is scarcely any well-attested evidence of these plants ever acquiring any considerable age. It has indeed been supposed, that certain Brazilian cocoa-nut palms may be from 600 to 700 years old, and that others probably attain to the age of something more than 300 years. But the method of computing the age of palms, which is either by the number of rings externally visible upon their rind between the base and the summit of the stem, or by comparing the oldest specimens, the age of which is unknown, with young trees of a known age, is entirely conjectural, and not founded upon sound physiological considerations; besides which, the date-palm, which is best known to Europeans, does not at all justify the opinion that palms attain a great age; the Arabs do not assign it a greater longevity than from two to three centuries.

But in exogenous trees, it is quite the reverse: to their existence no limited duration can be assigned. Of the many remarkable cases upon record of a great age attained by exogenous trees, the following are among the more interesting.

At Ellerslie, the birth-place of Wallace, three miles to the S. W. of Paisley, stands an oak, in the branches of which tradition relates that celebrated chieftain to have concealed himself with three hundred of his followers. However improbable the latter circumstance may be, it is at least certain that the tree may well have been a remarkable object, even at the period assigned to it by tradition, namely, in the beginning of the fourteenth century, and if so, this individual must be at least 700 years old. Its branches are said to have once covered a Scotch acre of ground; but its historical interest has rendered it a prey to the curiosity of the stranger, and the limbs have gradually disappeared till little remains except the trunk. Many other cases of oaks of extreme old age are recorded, some of which have been estimated at 1500 or 1600 years.

Of ancient yews several authentic instances can be named. At Ankerwyke House, near Staines, is a yew older than the meeting of the English barons at Runnymede, when they compelled King John to grant the Magna Charta. This tree, at 3 feet from the ground, measures 9 feet 3 inches in diameter; and its branches overshadow a circle of 207 feet in circumference. The yews of Fountain's Abbey, in Yorkshire, are probably more than 1200 years old; and to others an age of from 2500 to 3000 years has been assigned.

Even this degree of antiquity is, however, much less than that of the baobab trees of Africa, estimated by Adanson at 5000 years; and the deciduous cypress of Chapultepec in Mexico, which the younger De Candolle considers still older.

The way in which the age of some of these specimens has been computed is twofold: firstly, by comparing them with other old specimens, the rate of growth of which is known; and secondly, by cutting out a portion of their circumference, and counting the number of concentric rings that are visible; for in exogenous trees the woody cylinder of one year is divided from the succeeding one by a denser substance, which marks distinctly the line of separation of the two years. The first of these methods is sufficiently correct to give at least an approximation to the truth, and the latter would be absolutely correct, if one could be quite sure that observers provided against all possible causes of error. But it has been shown by Dr. Lindley, that in consequence of the extreme inequality in thickness of the annual layers of wood on opposite sides of a stem, a person who judged of the whole age of a tree by the examination of the layers of the stunted side only, would commit errors to the amount of sixty per cent. and more. It is by no means impossible that the great age assigned to the deciduous cypress and the baobab may be connected with an error of this nature.

AGENT. In commercial matters, where one person acts for another, he is called an *agent*, and his employer the *principal*. The relations between the two are of great importance, and are guided in some respects by statutes, and in others by the custom of the particular department of commerce to which they belong.

AGIO, a term used sometimes to express the variations from fixed pars or rates of exchange, but more generally to indicate by per centages the differences in the valuations of moneys. The Italian word *aggio* is explained to mean 'an exchange of money for some consideration.' Thus, if a coin is reduced in weight, and the real value is not equal to the nominal value, the difference is the agio.

Where it is in the power of the state to prevent the degradation of the coin below the standard, no calculations of agio, strictly so called, are rendered necessary. In some states, the currency is made up of the deteriorated coins of the neighbouring countries with which the inhabitants have dealings. Under these circumstances, banks were, at different times, established by the governments of Venice, Genoa, Hamburg, Amsterdam, &c., which, under the guarantee of the state, should be at all times bound to receive deposits and to make payments, according to some standard value. The money or obligations of these banks bears a premium equivalent to the deterioration, and this premium is called the agio of the bank.

As the current coins of every country have a kind of medium value at which they are generally taken, the term agio is also applied to express what must be paid over and above this medium value. The kinds of money on which, in the case of exchange, an agio is paid, are not always the more valuable intrinsically, but those which are most in request.

The term agio is also used to signify the rate of premium which is given, when a person having a claim which he can legally demand in only one metal, chooses to be paid in another.

Thus, in France, silver is the only legal standard, and payments can be demanded only in silver coin: a circumstance which is found to be practically so inconvenient, that the receiver will frequently pay a small premium in order to obtain gold coin, which is more easily transportable: this premium is called the agio on gold.

AGRICULTURAL IMPLEMENTS. A large and important department of manufacturing skill is that which is devoted to agricultural implements and machines—to those mechanical aids by which the produce of the soil is developed. Like most other departments of industry, this has made a great advance within the last few years. The researches of Liebig, Boussingault, Thaer, and other foreign experimentalists, and those of our own countrymen, have taught us what are the relations which each kind of soil bears to each species cultivated, and how the mechanical preparation of the soil can most efficiently be carried on. Our Smithfield cattle shows, and the annual exhibitions of the Royal Agricultural Society, demonstrate how much attention is now paid to the form and manufacture of agricultural implements.

The Comte de Gasparin, in his valuable *Cours d'Agriculture*, presents a useful analysis and classification of agricultural implements, according to the nature of the operations which they are destined to perform. First come *perforating* implements, intended simply to make holes in the ground, generally for the reception of roots or seed; these comprise the single and double dibble, a frame with pointed spikes, a roller with pointed spikes, and other contrivances of a similar kind. The second class comprises implements which *cut* the soil in strips, or *loosen* it in rows; these comprise ploughs, harrows, rakes, scarificators, &c. In the third class are implements used to cut the soil into horizontal *slices;* these are illustrated by paring machines, by turf-cutting machines, by many forms of plough-share, and by extirpators. The fourth class comprises implements which *overturn* long strips of soil upon themselves; among these are to be numbered cultivators, and many minor forms; indeed the plough itself in some of its forms belongs to this class, inasmuch as it exposes new portions of soil to the action of the atmosphere. The fifth class comprises the more complete forms of plough, by which three movements are effected—a vertical cut, a horizontal cut, and an overturning of the portion loosened. In the sixth class are instruments which displace the soil in separate pieces, and not in continuous strips; they comprise spades, pick-axes, hoes, pitchforks, and other simple hand-worked tools. The seventh class comprises implements used in crushing, equalising, smoothing, and pressing the clods which have been loosened by any of the before mentioned means; the various kinds of clod-crushers, rammers, and rollers are included in this class. In the eighth class are comprised the numerous varieties of *sowing* machines, from the simplest to the most complicated drills, &c. The ninth class comprises the *harvesting* or *reaping* machines, such as sickles, scythes, &c.

Gasparin goes on to the formation of other classes; such as implements for preparing grain for the market (flails, thrashing machines, winnowing machines, &c.); implements of transport (baskets, wheelbarrows, and vehicles of every description used upon a farm); and machines of any kind used in irrigation.

Under their proper headings in this Cyclopædia, all the principal agricultural implements are described. There may be many readers who are not aware that the manufacture of such implements has assumed a magnitude and systematic character quite analogous to the great factory system. At the works of Messrs. Ransome and May, for example, at Ipswich, the operations are conducted on a gigantic scale, and with all that subdivision of labour which marks an advanced stage in manufactures. Many hundred persons are here constantly employed in the manufacture of agricultural implements and machines. Mr. Allan Ransome, a partner in this firm, has within the last few years published a valuable illustrated treatise on such implements.

AGRICULTURAL INSTITUTIONS. The Board of Agriculture was established chiefly through the exertions of the late Sir John Sinclair, and was incorporated in 1793. One of its first proceedings was to commence a survey of all the English counties on a uniform plan. The 'Surveys' were useful at the time in developing more rapidly the agricultural resources of the country. During the years of scarcity, at the end of the last and beginning of the present century, the Board of Agriculture took upon itself to suggest, and as far as possible provide, remedies for the dearth, by collecting information and making reports to the government on the state of the crops. The statistics which the board collected were also at times made use of by the minister, or at least were believed to be so, in connection with his schemes of taxation. The board encouraged experiments and improvements in agriculture by prizes, and it naturally exercised considerable influence over the provincial agricultural societies.

The Board of Agriculture was dissolved in 1816.

The Smithfield Cattle Club, which has been in existence half a century, and some of the provincial agricultural societies, especially the Bath and West of England Society, which commenced the publication of its 'Transactions' nearly seventy years ago, have been very useful in promoting agricultural improvement.

With the establishment of the 'Royal Agricultural Society of England,' a new æra commenced in the history of institutions for the improvement of English agriculture. The objects of this society, as set forth in the charter of incorporation, are:—1. To embody such information contained in agricultural publications and other scientific works as has been proved by practical experience to be useful to the cultivators of the soil. 2. To correspond with agricultural, horticultural, and other scientific societies, both at home and abroad, and to select from such correspondence all information which, according to the opinion of the society, may be likely to lead to practical benefit in the cultivation of the soil. 3. To pay to any occupier of land or other person, who shall undertake, at the request of the society, to ascertain by any experiment how far such information leads to useful results in practice, a remuneration for any loss which he may incur by so doing. 4. To encourage men of science in their attention to the improvement of agricultural implements, the construction of farm-buildings and cottages, the application of chemistry to the general purposes of agriculture, the destruction of insects injurious to vegetable life, and the eradication of weeds. 5. To promote the discovery of new varieties of grain and other vegetables useful to man, or for the food of domestic animals. 6. To collect information with regard to the management of woods, plantations, and fences, and on every other subject connected with rural improvement. 7. To take measures for the improvement of the education of those who depend upon the cultivation of the soil for their support. 8. To take measures for improving the veterinary art, as applied to cattle, sheep, and pigs. 9. At the meetings of the society in the country, by the distribution of prizes and by other means, to encourage the best mode of farm cultivation and the breed of live stock. 10. To promote the comfort and welfare of labourers, and to encourage the improved management of their cottages and gardens. The country meetings take place annually in July. England and Wales are divided into nine great districts, and a place of meeting in each is fixed upon about a year beforehand.

The success of the Royal Agricultural Society has revived the spirit of existing associations, or led to the formation of new ones. There are now about four hundred agricultural societies in various parts of England. There are also a hundred and fifty farmers' clubs, which are eminently practical; and the local results which they collect and discuss may become applicable to other parts of the country placed under similar circumstances of aspect, soil, and situation.

The agriculture of Scotland has been largely indebted to the societies which have been established at different periods for its improvement. A 'Society of Improvers in the Knowledge of Agriculture in Scotland,' was established in 1723, and some of its transactions were published. The society becoming extinct, was succeeded by another in 1755; and the society which now stands in the same relation to Scotland as the Royal Agricultural Society to England was established in 1784. It is entitled the 'Highland and Agricultural Society of Scotland.' The constitution and proceedings of the society are as nearly as possible similar to the English society.

In 1841 the 'Royal Agricultural Improvement Society of Ireland' was established on the plan of the Royal Agricultural Society of England.

In England there are no institutions of a public nature which combine scientific with practical instruction in agriculture. The advantage of establishing such an institution was suggested by the poet Cowley; and in 1799 Marshall published 'Proposals for a Royal Institute or College of Agriculture and other branches of Rural Economy.' There is the Sibthorpian Professorship of Rural Economy in the University of Oxford; at the University of Edinburgh there are professorships of agriculture and agricultural chemistry; and at the university of Aberdeen there are lectures on agriculture. The botanical, geological, and chemical professorships and lectures in the different universities are, however, to a certain extent auxiliary to the science of agriculture. The Earl of Ducie has established a model example farm on his estate in Gloucestershire; and farms of this description are of considerable local advantage. There is one on a very complete scale at Harpenden, near St. Alban's, replete with all the apparatus for the chemical analysis of soils, fodder, products, &c. In 1839, the late B. F. Duppa, Esq., published a short pamphlet entitled 'Agricultural Colleges, or Schools, for the Sons of Farmers,' which contains many useful suggestions for the establishment of such institutions. In the Agricultural College and Model Farm at Cirencester the pupils receive an education at once practical and scientific, under a person thoroughly acquainted with the management of a farm, associated with a professor of chemistry, mechanics, &c.

In Ireland the government affords direct encouragement to agricultural education through the instrumentality of the Board of National Education. The persons who are trained for the office of teachers in the national schools are required to attend the lectures of a professor of agricultural chemistry. The Agricultural Seminary at Temple-Moyle, six miles from Londonderry, is one of the most successful experiments which has yet been made in the United Kingdom to establish an institution for agricultural education. It was founded by the North West of Ireland Society in 1827, and up to 1840 had been attended by 418 pupils.

Such societies as the Scottish Agricultural Chemistry Association, established at the close of 1843, are very well calculated to advance the progress of scientific agriculture; and they can be established in any district where a sufficient number of subscribers can be obtained to command the services of a competent chemist. Associations of this nature show how much can be done in this country without any assistance from the state. Landed proprietors who subscribe twenty shillings yearly, are entitled to have performed analyses of soils, manures, &c., according to a scale fixed upon; and if more than a certain number are required, a charge of one-half above the scale is made.

In England, soils are analysed at the Museum of Economic Geology, London, at a charge of one guinea. The establishment is under the superintendence of her Majesty's office of Woods and Forests.

In France there are schools assisted by the state, where young persons can obtain instruction in agriculture, both practical and theoretical. The principal institution of this kind is that at Grignon, where one of the old royal palaces and the domain attached to it, consisting of 1,185 acres of arable, pasture, wood, and marsh land, have been given up on certain conditions. The professors are paid by the government, and the pupils are of two grades, one paying 48*l.* a year, and the other 30*l.* For the purpose of imparting theoretical knowledge, courses of lectures are given on the following subjects:—1. The rational principles of husbandry, and the management of a farm. 2. The principles of rural economy applied to the employment of the capital and stock of the farm. 3. The most approved methods of keeping farming accounts. 4. The construction of farm-buildings, roads, and implements used in husbandry. 5. Vegetable physiology and botany. 6. Horticulture. 7. Forest science. 8. The general principles of the veterinary art. 9. The laws relating to property. 10. Geometry applied to the measurement and surveying of land. 11. Geometrical drawing of farming implements. 12. Physics, as applied to agriculture. 13. Chemistry as applied to the analysis of soils, manures, &c. 14. Certain general notions of mineralogy and geology. 15. Domestic medicine, applied to the use of husbandmen.

Institutions designed for the improvement of agriculture, and supported by the state, have been established in most parts of Germany. In Prussia there is a public model farm and agricultural academy in nearly every province. The most important of these institutions is the one at Mogelin, in Brandenburg, about 40 miles from Berlin, which was founded by the late king. The establishment consists of a college and a model farm of 1200 acres. At Hohenheim, in the kingdom of Wirtemberg, two leagues from Stuttgard, an old palace has been appropriated as an agricultural college. The quantity of land attached to the institution is about 1,000 acres. Lectures are delivered by twelve professors on the following subjects:—Mathematics and physics, chemistry and botany, technology, tillage, and other departments of rural economy, forestry, and the veterinary art. In Bavaria the king has given up the domain attached to the royal palace of Schleissheim for the purposes of a model farm.

There are agricultural institutions supported by the state in several other countries of Europe.

AGRICULTURE. Without attempting any formal treatise on agriculture, useful details will be met with under the names of the chief agricultural instruments and the chief vegetable crops. In several countries of Europe there is a department of government organized either for collecting the statistics of agriculture or superintending institutions which have immediate relation to that branch of industry. In France these duties devolve upon a department of the Minister of Commerce and Agriculture. The councils general of agriculture, &c., in each department of France collect the agricultural statistics from each commune; and the quantity of land sown with each description of grain, the produce, and the quantity of live stock for the whole of the kingdom, are accurately known and published. In Belgium these facts are ascertained periodically, but not every year. In the United States of North America, at the decennial census, an attempt was made to ascertain the number of each description of live stock, including poultry; the produce of cereal grains, and of various crops; the quantity of dairy, orchard, and garden produce, &c., in each State. There are twenty nine heads of this branch of inquiry. The only countries in Europe which do not possess statistical accounts of their agriculture founded on official documents are England and the Netherlands. On the same principle that a census of the population of a country is useful, it must be useful to have an account of its productive resources. The absence of official information is supplied by estimates of a conjectural character, founded at best only on local and partial observation. In France it is positively ascertained that the average produce of wheat for the whole kingdom is under fourteen bushels per acre. In England it is known that the maximum produce of wheat per acre is about forty bushels, and that the minimum is about twenty bushels. The usual conjecture is that the average produce of the kingdom in years of fair crops is about twenty-eight bushels, but the total superficies sown with wheat or any other grain, and the total quantity of the produce, are matters simply of conjecture. It would be most desirable to trace what have been the results of the more scientific cultivation of the last few years. The only statement the public or even the government are in possession of in respect to the quantity of land cultivated and uncultivated, and of land incapable of producing grain or hay, in Great Britain, rests upon the authority of private inquiry made by one person, Mr. Couling, a civil engineer and surveyor, who gave the details to the parliamentary committee on emigration in 1827. From his tables it appears that upwards of forty-six millions of acres were cultivated in the United Kingdom; of which about nineteen millions were cultivated as arable and gardens, and about twenty-seven millions were meadows, pastures, and marshes.

AIGLETS is the French name for what in England are called *tags*, viz., the metal sheaths at the end of laces or points. These *points* are now out of date; they were ties or bows, adorned at the ends with aiglets, and were used instead of buttons for fastening dresses. They were, in the 16th and 17th centuries, not used merely for service, as the modern tag, but were profusely employed as ornaments, glittering like spangles.

In some of the silk-mills of Derby, tags for silk boot-laces are made in a curious manner. A little boy sits before a kind of cutting-machine, with which he cuts a strip of sheet-brass into small pieces, each large enough for one tag; the piece is at the same time bent into a kind of semi-cylindrical form. The pieces are then taken up by another boy, and dropped one by one into a recess in another machine; and the end of a silk-lace being laid in the hollow of a tag, a lever is brought down with the left hand, by which the tag is made to embrace the lace firmly, enclosing it all round. These processes are conducted with astonishing rapidity: the fingers of the two boys moving almost as fast as the eye can follow them.

AIR, is the material of our atmosphere, though in the last century the name was applied to gases of most kinds as fast as they were discovered. The air which envelops the globe is a *mixture* (not a chemical compound) of oxygen and nitrogen, with a very small proportion of carbonic acid, and water in the state of vapour. The two last are considered as accidental ingredients, and not constituent parts; as well on account of the smallness of their quantity, as because they occur in different proportions at different times. Estimated by weight, air is found (nearly, but not with strict accuracy) to consist of one atom or equivalent of oxygen to two of nitrogen; or, estimated by volume, the oxygen is to the nitrogen in the ratio of one to four. The carbonic acid and aqueous vapour, taken together, are not more than one-fiftieth of the whole weight. A thousand cubic inches of dry air, the barometer standing at 30 inches, and Fahrenheit's thermometer at 60°, weigh about 310 grains. The same bulk of water, at the same pressure and temperature, weighs 252,525 grains, or more than 800 times that of air.

The air, in common with all other bodies, has weight. This is proved by weighing a bottle which contains air in a very delicate balance, and then by repeating the process after the air has been exhausted from the bottle by the air-pump. From this we are immediately led to conclude that, like all other heavy fluids, air exercises pressure upon all substances which are in contact with it,—a truth that was very little suspected in ancient times. The density of the air depends upon, and is a consequence of, the pressure of the superincumbent atmosphere; or the air is an elastic fluid; that is, its bulk increases, and its density diminishes, whenever the exterior pressure is wholly or partially removed. Let a loose bladder, tied at the mouth, and not so full of air as to be distended, be placed under the receiver of an air-pump, so that the air which presses the outside of the bladder can be exhausted; the interior air will expand so soon as the exhaustion begins, will presently distend the bladder to its fullest dimensions, and in some cases will even burst it. On the re-admission of the air into the space surrounding the bladder, the latter will gradually resume its former dimensions, and its withered or flaccid appearance. As we ascend the atmosphere, the superincumbent column of air becomes of less weight, and the density becomes less; that is, a cubic foot at the height of (say) 1000 feet above the ground is not so heavy, or does not contain so much air, as a cubic foot at the surface of the earth. The pressure and density of the air are regulated by the following law: *at the same temperature*, the elastic forces of two portions of air (or, which is the same thing, the weights of mercury they will balance) are in direct proportion to the densities, or in inverse proportion to the spaces, occupied by these portions. The human body would be crushed by the pressure of the air on it, were there not a counter pressure from within.

The temperature of air influences its elastic force. It is probable that air would become first liquid, and then solid, if it could be made sufficiently cold. Like all other substances, air gives out heat when it is compressed; a property strikingly illustrated by the fact that tinder can be set on fire when the air in which it is contained is suddenly and violently compressed.

Air, like gases and vapours generally, enlarges its bulk with every increase of temperature, or increases its elastic force if enlargement of bulk be prevented. The quantity of this expansion, when the temperature passes from the freezing to the boiling point of water (that is, from 32° to 212° of Fahrenheit's thermometer, from 0° to 80° of Réaumur's, and from 0° to 100° of the Centigrade), is 375 parts out of a thousand of the bulk which it had at the freezing point. And this enlargement is uniform; that is, whatever expansion arises from an increase of 12° of temperature, half as much arises from an increase of 6°, twice as much from one of 24°, and so on. From the different systems on which the Fahrenheit, Réaumur, and Centigrade thermometers are graduated, it follows that the increase of bulk, corresponding to a rise of *one* degree of temperature in the air (the bulk of 32° F. being taken as a standard) is equal to $\frac{1}{480}$, $\frac{3}{640}$, $\frac{3}{800}$ respectively. In some few cases this regularity of expansion is not quite certain, but it is known to be very near the truth.

On the properties of air with regard to other bodies, we may notice that probably there is a slight adhesion of air to many, if not to all surfaces. A small needle may be made to swim on water, and in this state the water evidently retires from around it, leaving it, as it were, suspended over a hollow in the fluid. This is attributed to the adhesion of a coat of air, which, with the iron, makes the whole specifically lighter than the water. Recent experiments on the pendulum have led some to suspect, that, in addition to the resistance of the air, a slight coating of this substance travels with the pendulum, and thereby causes an irregular addition to its weight.

These few details concerning the general properties of air will meet with various illustrations under AIR-GUN; AIR-PUMP; ATMOSPHERE; BALLOON; COMBUSTION; PNEUMATICS; STOVE; VENTILATION, &c.

AIR-BEDS and CUSHIONS. [WATER-PROOF COMPOSITIONS.]

AIR-BLADDER. Cod-sounds, which are brought in great quantities from Newfoundland, are nothing more than the salted air-bladders of these fishes. The Iceland fishermen, as well as those of America, prepare isinglass of a very excellent quality from cod-sounds; though they are not acquainted with the method of clarifying it, which the Russians practise in preparing that article from the sound of the sturgeon. [ISINGLASS.]

AIR ENGINES. Many attempts have been made within the last few years to produce engines which should have the power of steam-engines without the use of steam. The compression or the rarefaction of air, brought about in some one of many different ways, is the agent relied upon for producing a moving force. In 1840 Mr. Stirling patented such a machine, and read a description of it before the Institute of Civil Engineers in 1846. In this engine two strong air-tight vessels are connected with the opposite ends of a cylinder, in which a piston works in the usual manner. About four-fifths of the interior space in these vessels is occupied by two similar air-vessels, or plungers, suspended to the opposite extremities of a beam, and capable of being alternately moved up and down to the extent of the remaining fifth. By the motion of these interior vessels the air to be operated upon is moved from one end of the exterior vessel to the other; and as one end is kept at a high temperature, and the other as cold as possible, when the air is brought to the hot end, it becomes heated, and has its pressure increased, whereas its heat and pressure are diminished when it is forced to the cold end. Now as the interior vessels necessarily move in opposite directions, it follows that the pressure of the enclosed air in the one vessel is increased, while that of the other is diminished; a difference of pressure is thus produced upon the opposite sides of the piston, which is thereby made to move from one end of the cylinder to the other; and by continually reversing the motion of the suspended vessels or plungers, the greater pressure is successively thrown upon a different side, and a reciprocating motion of the piston is kept up. The piston is connected with a fly-wheel, in any of the usual modes, so as to communicate motion to machinery. There is a furnace to heat one end of the air-vessels, and a water-pipe refrigerator to cool the other; and the air traverses numerous small channels in its course from the one end to the other, in such a mode as to economise the heat. An engine on this construction has been used in an iron foundry at Dundee.

One of the most remarkable projects for an air-engine is the *Carbonic Acid Locomotive*, for which Mr. Baggs took out a patent in 1842. Carbonic acid gas assumes a liquid form under a pressure of about 540 lbs. to the inch, at a temperature of 32°; and the project consists in an attempt to make the sudden vaporisation of this liquid a source of power. Carbonate of ammonia is made by one of the usual chemical processes; and this being separated into its proximate elements of carbonic acid gas and ammoniacal gas, these two gases are brought to the liquid state, either by the chemical method of Mr. Faraday or the mechanical method of Sir M. I. Brunel. The locomotive or other engine is charged with the condensed or liquefied gases, which are contained in very strong wrought iron tubes; and on opening certain valves, the liquids suddenly flash into the vaporic form, mix and combine together, and are condensed into carbonate of ammonia in an adjoining condenser. This carbonate of ammonia can be again used as a source whence to obtain the two gases. The sudden force generated when the liquids expand into vapour, becomes a moving power for the machine. Apparatus must be provided at suitable stations, for making the two gases, and condensing them into the liquid form.—Such is the rationale of this singular scheme; but we are not aware that it has proceeded beyond the specification of the patent.

Mr. H. Pratt published a pamphlet, about 1845, with a view of shewing that the ascensive force of a lofty current of air, when aided by heat, may be applied to the moving of machinery. The common smoke-jack, and many other machines long in use, illustrate the force of an ascending column of heated air; but Mr. Pratt's object is to show that there is an ascensive power in a tall current of air more than equal to the result produced by the heating of the air to a temperature beyond that of the external atmosphere. A large bakery has been established on this principle at New York, the machinery being worked by the ascensive force of a current of air heated by the baking ovens. At a certain height within a lofty vertical shaft is a horizontal wheel, with wings or vanes attached at an angle of 10°; the ascending air causes this wheel to revolve horizontally; drums are fixed on the spindle of the wheel, and straps or bands from these drums drive the machinery for grinding the flour and kneading the dough. The dimensions of the various parts are so calculated as to produce about 200 horse-power.

Baron Von Rathen made trial of an air-locomotive on a common road, in 1848. It travelled from Putney College (where it was constructed) to Wandsworth, at the rate of 10 or 12 miles an hour. The air-reservoir (substitute for a steam boiler) had a capacity of 75 cubic feet; it was capable of being charged with air to a pressure of fifty atmospheres, by a 6-horse power engine.

AIR-GUN, an instrument for projecting bullets, in which the moving power is the rush of condensed air allowed to escape, instead of the formation of gases arising from the ignition of gunpowder.

In the stock of the air-gun is a condensing syringe, the piston of which condenses air into a cavity having a valve opening inwards, just behind the bullet. The barrel is open, and the bullet (which should just fit the barrel) is inserted in the usual way. The trigger opens the valve behind the bullet, and permits the rush of the condensed air, which propels the bullet forward. The moment the finger is withdrawn from the trigger, the air closes the valve, and remains, somewhat less condensed than before, for the next discharge.

The same principle has been variously applied. In the magazine air-gun, there is a reservoir of bullets, in a channel under the barrel, one of which is turned in by a cylindrical cock pierced by a tube, which in one position is a continuation of the reservoir of bullets, and in another, of the barrel. Thus by turning the gun upside down, and turning the cock, a bullet falls into it from the reservoir, which, on returning the cock, is of course in the barrel. In some air-guns, the cavity containing the condensed air is a hollow copper ball, which can be screwed on to the gun after condensation. The *Air-Cane* is so called because it is usually in the form of a walking stick. The handle contains the condensed air, and can be unscrewed and filled by a separate condensing syringe.

No power, but only a convenient adaptation of power, is gained in an air-gun; since the condensation of the air itself requires an expenditure of power. The instrument has hitherto been little more than a toy.

In 1849 a singular air-gun was invented, in which the elastic quality of gutta-percha was brought in aid of the elasticity of air, so as to charge the gun without the necessity for a condensing syringe—such, at least, was the theory of the apparatus.

AIR-PUMP, is an instrument for removing the air out of a vessel. It effects the reverse operation to that performed by the *condensing syringe*, by which additional air is forced into a vessel. Both in the exhausting and the condensing syringe there is a tube closed at one end, excepting an orifice to which a valve or lid is attached. A piston, with a rod and handle, enters at the other end, and can be moved up and down the tube. The piston is not entirely closed, but has a valve opening the same way as the other valve. Both are attached to vessels, the air of which is to be rarefied or condensed. In the exhausting syringe, both valves open upwards or let air only *out* of the vessel and the piston: in the condensing syringe, both open downwards, or let air only *into* the vessel and the piston. In the exhausting syringe, every time that the piston is drawn *upwards*, it leaves a sort of vacuum in the barrel; and the air in the receiver forces up the lower valve to fill up this vacuum. At the next movement, the air thus raised is driven ont of the instrument altogether; for the valves are so placed that no air can go from above downwards. By repeated movements of this kind, nearly all the air may be drawn out of the receiver. In the condensing syringe, all the operations are exactly reversed; the *downward* motion of the piston being the efficient agent in forcing into the receiver a quantity of air many times greater than that which it originally contained.

The exhausting syringe is, in principle, the common air-pump. In most forms of air-pump there is at the top a metal plate ground to a perfectly plane surface, on which is placed an inverted glass jar or receiver, whence the air is to be extracted. A hole in the plate is connected with a tube, which communicates with two pump barrels. These barrels are exhausting syringes. One or more guages are attached to the instrument to test the degree of exhaustion of the air. The pistons which work in the two pump-barrels are connected by a rack-and-pinion movement with a handle, in such a way that when the handle is worked in semi-circular movements, the pistons are raised alternately. As the lower part of each barrel is connected with the receiver by means of the tube, the movements of the two pistons gradually draw out the air from the receiver, in the manner of the exhausting syringe; and in this way a nearly perfect vacuum may be produced.

In most of the objects for which an air-pump is required in scientific experiments, a glass receiver, provided with stop-cocks or other adjustments, is placed on the plate of the air-pump to have the air extracted; aud experiments or observations are made in the vacuum thus produced.

If the receiver of an air-pump be open at both ends, and the upper orifice be stopped by the hand,—on exhaustion, the pressure of the exterior air will be painfully great on the hand. If a piece of bladder be tied tightly over the orifice, as the exhaustion proceeds the bladder will be pressed inwards, and will finally burst with a loud noise. The weight of the air is proved by exhausting a copper ball furnished with a stop-cock, which is shut before the ball is removed from the air-pump: it will then be found to weigh less than before the exhaustion was made. The presence of air in various substances may be detected by means of an air-pump. A glass of liquid placed under the receiver will give out bubbles of air as soon as the exhaustion begins. A shrivelled apple will be restored to apparent freshness by the expansion of the air which it contains; but will resume its original appearance when the air is allowed to return. The elasticity of air may be shown by placing a bladder under the receiver, not distended, and the mouth of which is tied up; on exhausting the receiver, the air contained in the bladder will expand it more and more, as more of the pressure from the exterior is removed; and the bladder will finally burst from the interior pressure. If a hole be made in the smaller end of an egg which is placed under the receiver, the small bubble of air, which is always found in the larger end, will by its expansion force out the contents of the egg.

In machinery employed in manufactures, the air-pump is applied in various ways, especially with some forms of steam-engines. In such cases no glass-receiver is necessary, and the mechanism of the air-pump is larger and stronger.

AIR-SADDLE. The principle of the air vessel has been applied within the last few years to the production of saddles: the leather being made into a hollow case, and inflated with air, as a means of forming an easy seat for the rider. A patent was taken out for the invention; but it may be doubted whether the jolting action to which a saddle is subjected would not be too severe for an air-stuffed case.

AIR-VESSELS, or *Air-Chambers*, are used in various machines, either to regulate and equalise the propulsion of fluids, as in a FIRE-ENGINE; or to regulate and check the velocity of apparatus which might otherwise attain a dangerous degree of speed. An example of the last-mentioned use is afforded by the contrivance employed by Mr. Timothy Bramah, instead of a fly, to regulate the speed of a tread-mill. In this contrivance the turning of the tread-wheel is made to work a series of large bellows, or air-vessels resembling bellows, in which the apertures for the ingress and egress of air are fitted with sliding plates worked by an apparatus resembling the governor of a steam-engine; so that whenever the speed of the machinery exceeds the desired limit, the apertures are reduced, and a greater resistance is thereby occasioned. Similar contrivances, in which a cylinder and piston may be used instead of bellows, and water or oil instead of air, may be advantageously employed in lieu of ordinary breaks for cranes used in lowering heavy goods, and in various other machines.

AIRDRIE has lately sprung up to be the centre of one of the most important mining districts in Scotland. It is situated about a dozen miles east of Glasgow. The whole district beneath and around Airdrie abounds in the richest ironstone and coal; and some of the largest iron-works in Scotland are here located, around which a numerous population of miners and workpeople is accumulating. Airdrie is connected with Glasgow by the Monkland Canal and by the Caledonian Railway, by which routes its mineral treasures reach the great emporium of Scottish commerce.

AIX, a considerable town of France, in the department of the Bouches du Rhone, carries on an important trade in hardwares, fish, and the productions of the neighbouring country. Among the manufactures are silks, velvets, woollen cloth, and printed calicoes.

ALABA'MA, one of the southern United States of North America, is a flourishing seat of commerce and industry. The forest trees in the middle and north of the state, are post oak, white oak, black oak, hickory, poplar, cedar, pine, chestnut, and mulberry; in the south, pine, cypress, and loblolly. Iron ore is found in various parts of the state, and coal is abundant on the Black Warrior river and the Cahawba river. Cotton is the staple production of the state, but Indian corn, rice, wheat, oats, &c., are produced. The Alabama river is navigable for vessels drawing six feet water, 60 miles above its junction with the Tombigbee, to Claiborne, and has four or five feet water for 150 miles farther, to the mouth of the Cahawba. The Tombigbee is navigable for small sailing vessels to St. Stephens, 150 miles, and for steam-boats to Columbus in Mississippi State; its total length is 450 miles, and it is navigable for boats nearly the whole length. Cotton is the great article of export. The city and port of Mobile is, next to New Orleans, the largest cotton-mart of the southern states, 320,000 bales having been exported in a year. 40,000 bales, of about 500lb. each, are annually shipped from Montgomery in this State.

Manufactures are spreading considerably in this state. Tanneries, iron-foundries, cutleries, distilleries, printing-offices, &c., are rapidly increasing. Since the collisions of opinion between the northern and southern states respecting slavery, the latter have begun to erect cotton mills as a means of fostering their own cotton culture; and Alabama, as one of them, is rising in importance. In the middle of 1850 there were in Alabama 12 cotton mills, with 12,580 spindles and 300 looms; and there were then contracts in force for 20,000 more spindles and 550 more looms. The exports from Alabama in 1848 were valued at 11,927,749 dollars. The population of Alabama has risen from 20,845 in 1810, to 624,827 in 1845. The railways in Alabama at the beginning of 1849 were 113 miles in length, viz., from Montgomery to West Point, and from Tuscumbia to Decatur.

ALABASTER, is a delicate white soft kind of marble, used for ornamental purposes. The name is derived from Alabastron, a town of Egypt, where there appears to have been a manufactory of small vessels or pots, made of a stone found in the mountains near the town.

There are two kinds of alabaster: the one is a *carbonate* of lime; the other is gypsum, or *sulphate* of lime. Many of the ancient perfume vessels are made of the compact crystalline mass deposited from water holding carbonate of lime in solution, which is found in many places in almost every country. It is easy to ascertain of which of the two kinds a vessel is composed; for *carbonate* of lime is hard, and effervesces if it be touched by a strong acid; but *sulphate* of lime does not effervesce, and is so soft that it may be scratched with the nail. The term alabaster is now generally applied to the softer stone. This last, when pure, is a beautiful semi-transparent snow-white substance, easily worked into vases, lamps, and various other ornaments; but it is seldom found in masses large enough for statuary; and, indeed, artists would be unwilling to execute any great work in a material so very liable to injury. It is largely found in Italy and in Derbyshire.

There are many ingenious modes of producing slight modifications in alabaster, in respect to colour or some other of its properties. Alabaster may be *bronzed*, by coating it once or twice with size, and touching it with a bronze powder, of which many different varieties are manufactured. By a judicious use of bronzing, very pleasing effects may be produced in an alabaster statuette. Alabaster may be *cleaned*, by washing with soap and warm water, and rinsing. It may be *polished*, by rubbing it with dried shave-grass, then with a paste of lime and water, and lastly with powdered talc. It may be *hardened*, by coating the surface with a mixture of plaster of Paris and gum arabic; or by heating, cooling, steeping in water, drying, and polishing. It may be *stained* by the same materials and in the same way as marble. It may be *cemented* when broken by a mixture of quicklime and white of egg. And lastly, it may be *etched* by covering it with an etching-ground composed of white wax, white lead, and oil of turpentine, and proceeding in the customary method of the etching process.

The alabaster manufacture is one of some importance in Italy. It employs numerous turning-lathes in Florence, Leghorn, Milan, and other towns. At Florence, especially, the beauty and uniformity of the alabaster enable it to be worked into ornaments of considerable size. The larger masses are cut with steel saws into blocks and pieces of various shapes, which are afterwards worked into the desired form by lathes and tools. Rasps, fine files, fine chisels, and graving tools, are the chief aids employed.

ALARUM. It is curious to mark how much ingenuity has been displayed within the last few years in the invention of alarums, and how many patents have been taken out for the inventions. In all such contrivances there is some little bit of mechanism or other which gives a shrill sound whenever attention is required to be directed to any subject with which the alarum is associated.

Without describing any of the older forms, we may glance at a few of the modern suggestions. A Mr. Allen, in 1844, registered an alarum intended to prevent injury to boilers from the water falling below its proper level. The machine consists of a float within the boiler, a steam-whistle on the exterior, and a tube of connection. When the water is at a proper height in the boiler, the float is buoyed up, and the whistle is silent; but when the water, and with it the float, descends too low, a little valve in the tube opens, and a current of steam from the boiler ascends to the whistle, which immediately gives forth a shrill sound, thereby indicating that the water has sunk too low in the boiler.

The alarums suggested within a recent period for use on railways, are exceedingly numerous. One patented by Mr. Doull, is a railway whistle, so constructed as to yield several notes, capable of being combined into a code of signals. A chemical alarum by Mr. Mowbray consists of a copper cylinder, with a whistle at the top. A piece of carbonate of lime and a little muriatic acid are put into the cylinder, by which carbonic acid gas is speedily generated; and this is forced by some kind of mechanism into the whistle, whenever a sound is required to be produced. A contrivance by Mr. Hoare, described before the Society of Arts, consists of a chain of rods extending from end to end of a railway train, and moving freely on joints. At the end of the chain, in the guard's carriage, is a crank which, when the rods rotate on their axes, comes in contact with a hammer, and causes it to strike a bell. The driver, or the passengers in any carriage, can give a slight rotatory motion to the rods, and thus signals be communicated.

But the busiest contriver of alarums, perhaps, is Mr. Rutter, who has called to his aid the marvels of electricity. In a patent for several such contrivances, taken out by him in 1847, one variety is the *Fire Alarum*, a complicated apparatus intended for use in large buildings. A galvanic battery is placed in one room, the alarum in another, thermometers in every room, and copper wires to connect all these pieces of apparatus. If the temperature of any room be greatly raised, as by accidental fire, the rising mercury in the thermometer comes in contact with a metallic wire, which sets the galvanic battery in action, and this again works the alarum-bell in the same way as an electro-telegraphic clock, but with an adjustment intended to show in which room the rise of temperature has occurred. A second variety, the *Trespass Alarum*, depends for its action on the placing, near every door and window, of a tube containing mercury, open at the top; the opening or closing of the door or window brings a small wire into contact with the surface of the mercury, and this completes a galvanic connection with a battery in another room: all the parts of the apparatus may be the same as those in the fire alarum, except by having open tubes of mercury near doors and windows, instead of thermometers in each room. A third variety, the *Railway Alarum*, is intended to establish signals of communication between the guard and the engine-driver of a railway train. There is a copper wire carried through or upon or beneath each carriage, and connected with another in the adjoining carriage by a flexible metallic cord: the wire and cord being coated with gutta percha to secure isolation. There is thus a wire-communication from end to end of the train. The guard has in his box or seat a very small galvanic battery; and the engine-driver has a series of small studs connected with the rail on which his hand is usually resting. When the guard wishes to communicate with the engine-driver, he sends a slight galvanic shock through the wire to the spot on which the hand of the driver rests; and the duplication or variation of the shock may be made to indicate various signals.—It must be evident that great completeness and exactness would be necessary to render any of the above three kinds of alarum efficient for the purpose intended.

A floating alarum was suggested a few years ago by Mr. Hobbs, of Bristol, to be moored to a sunken rock or other dangerous place at sea. The centre of the machine is an air-vessel or buoy. At each end is a box in which a whistle is fixed, whose mouth is protected from the water. As the water of the sea circulates in certain parts of the interior of the machine, it drives the air alternately from one end to the other, and impels it through the whistles; and the more violently the sea rocks the floating machine, the louder will the whistles give forth their sound. The proposal of the inventor is to make the buoy and whistles of such dimensions that the sound may be heard some miles distant.

Many of the above good things remain in the form of mere suggestions, not yet practically carried out; and it must be owned that some of them are rather cumbrous and complicated.

ALBANIA, a country of European Turkey, stretching along the coast of the Adriatic and Mediterranian seas, is very rugged and mountainous, and has but few rivers of any note. Among the natural productions may be mentioned many species of oak; as the *quercus cerris*, which affords timber of good size and quality; and the Valonia oak (*quercus ægilops*), the acorns of which are used in dyeing, and supply an article of export from many parts of Turkey. Other trees are the chestnut, the plane, the cypress, the ash, the cedar, the pine, and the larch. The wild vine and the elder are also frequent on the mountains, and the woods and wastes nourish the Amphilochian peach, the Arta nut, and the quince. The cultivated fruits are the olive, which might be rendered more productive by better care; the vine, the pomegranate, the orange, the lemon, the mulberry, and the fig. The agricultural produce consists of barley, oats, maize, and other grains, tobacco, and cotton; some portion of it is exported. Horses, asses, cattle, sheep, and goats are reared, and are sold to the Ionian Islanders. The milk of the goats is made into cheese, a small quantity of which is exported; and their skins serve to hold wine (to which, however, they impart a strong flavour).

Agriculture is in a lowly condition. The plough is of simple construction, and in time of harvest they reap their corn, though with little skill, and they never mow it. The business of sowing and reaping is left to the women and to the aged. The young men fell timber or dress the vines. There are few arts or manufactures. The Albanians export a considerable number of capotes annually; and they produce some embroidery on velvet, stuff, and cloth, for which the country enjoys a better reputation than any other part of European Turkey; but this is the work of the Greeks of Joánnina, who are an industrious people, rather than of the Albanians.

The trade consists mainly in the exchange of natural productions for the manufactures of nations more refined. Oil, wool, wheat, maize, and tobacco, are sent to the kingdom of Naples, or to the Ionian Isles and Malta; and sheep, goats, cattle, and horses, to the Ionian Islands. Cotton wool and timber are exported from the Gulf of Arta; but the cotton is brought chiefly from Thessaly, and the timber from ancient Acarnania, on the south side of the gulf. The manufactured goods which they export are—capotes; gun and pistol stocks, mounted in chased silver, plain and gilt; and embroidered velvets, stuffs, and cloths. They import coffee and sugar from Trieste; knives, sword-blades, gun-barrels, glass and paper, from Venice; gold and silver thread, for embroidery, from Vienna; French and German cloth, coarse and ill-dyed, from Leipsic; and caps and a few other articles from various parts. The want of ready means of communication is a great impediment to traffic. Goods are conveyed by pack-horses, four or five of which are attached to each other by cords, and guided by one man.

ALBANY, a district situated at the eastern extremity of the colony of the Cape of Good Hope in South Africa. The bays and inlets along the coast of this district, are frequented by abundance of excellent fish fit for curing. A large natural salt pan is situated near the

Zondag River, in which the salt forms in masses four or five inches thick; this furnishes a supply of salt to the district. The most important part of the trade of Albany consists in the traffic carried on by licensed traders with the native tribes, beyond the boundary line of the colony. This trade is carried on through a wide extent of country, in the Kaffer territory. The principal articles procured in this manner are hides, horns, and ivory, together with a considerable number of live cattle. The attention of the settlers has, within the last few years been drawn to the improvement of the growth of wool; and during 1848 and 1849, many manufactories were established in the towns.

ALBATA, is the name given to one of the numerous varieties of *white metal*, now so largely used in many branches of manufacture at Birmingham. Many different mixtures or alloys will produce a white metal. For example, Mr. Parker obtained in 1844 a patent for five such compounds, all having the properties of whiteness and considerable malleability. One consists of zinc, tin, iron, and copper, in certain specified proportions; another of zinc, tin, and antimony; a third of zinc, nickel, iron, and copper; a fourth of copper, nickel, and silver; and a fifth of nickel, iron, and copper. It seems evident from the specification, that many different proportions of the ingredients may be adopted, in each of the above kinds. The mode of making white metal, of zinc 50, tin 48, iron 1, and copper 3, is thus described:—the iron and copper are first melted together in a crucible, and while in a fused state, the tin is added in such quantities at a time, that the iron and copper shall not become solid; the zinc is then added, and the whole well combined by stirring. The flux is composed of one part of lime, one part of Cumberland ore, and three parts of sal-ammonia. The alloy thus produced may be cast in sand or ingots for rolling.

See further in respect to these compound metals under Alloy.

ALBERT DÜRER. [Dürer.]

ALBUM (White), was a tablet on which the Roman prætor's edicts were written; it was put up in a public place. It was probably called album because the tablet was white. The word was also used to signify a list of any body of persons, as of the senators and of the júdices.

A book which is intended to contain the signatures, or short verses, or other contributions of persons of note or supposed note, is now called an album. The name is also given to a book which is merely intended as a repository for drawings, prints, verses, and such matters. Trifling as it may appear, an album, in the hands of a person possessing good taste, may be made a very graceful article of artistic decoration. Some modern specimens are extremely costly.

ALBU'MEN forms a constituent principle of plants and animals; and its essential properties are found to be the same from whichever kingdom of the organised world it is derived. It is found in the green feculæ of plants in general; in the fresh shoots of trees; in the sap of many plants; in the bitter-almond, the sweet-almond, and the emulsive seeds in general; but it exists in the greatest abundance in such vegetables as ferment without yeast, and afford a vinous liquor. But albumen exists much more abundantly in animals than in plants. It forms a constituent both of the animal fluids and solids. Of the animal fluids, it forms an essential part of the serum of the blood; it abounds in the fluid that moistens the surface of the internal cavities of the body and of the organs they contain; and it exists in large quantity in the watery fluid poured out into those cavities in the disease termed dropsy. White of egg is nearly pure albumen: when liquid it soon putrefies; but if carefully dried it may be long preserved. In the animal solids, albumen forms the principal part of the skin, of fibrin, the basis of muscle or flesh, and of the organs called glands. It is an intricate compound of carbon, hydrogen, oxygen, nitrogen, sulphur, and phosphorus.

The most remarkable property of albumen is its power of solidifying under circumstances which would rather tend to liquefy than to solidify most substances. White of egg shows white fibres at a temperature of 134° F., solidifies at 160°, and becomes horny at 212°. When mixed with water, a higher temperature is required for coagulation. Albumen is precipitated in white fibres, by agitating white of egg with alcohol. Galvanic action will also coagulate albumen. Many of the stronger acids and salts will have the same effect; and so delicate a test of the presence of this substance is the bichloride of mercury, or, as it is commonly called, corrosive sublimate, that if a single drop of a saturated solution of corrosive sublimate be let fall into water containing only the two-thousandth part of albumen, it will occasion a milkiness in the water, and produce a curdy precipitate.

Albumen is not, as a distinct substance, largely used in manufactures; but its presence in many natural substances greatly influences the manufacturing processes adopted. It is employed as a glaze, or species of varnish, and as a clarifier for wines and syrups. *Al-*

bumen powder is made by drying white of egg to a horny consistency, and reducing it to powder; it is in this state exported largely to the West India sugar plantations, where it is used to clarify sugar.

ALBURNUM, in plants, is that part of the stem of trees which timber merchants call *sapwood.* It is the newly-formed unchanged wood lying immediately below the bark, and is always of a very light colour. It consists of little besides vegetable tissue; in which respect it differs from *heartwood* or *durâmen*, which is vegetable tissue combined with solid secretions, the nature of which varies with the species.

While many plants have the alburnum and heartwood distinctly separated, there are others, technically called white-wood trees, which consist of nothing but alburnum. This arises from their not forming any solid secretions which can give durability to the central parts; hence all such trees are quickly perishable.

ALCARRAZAS. [COOLER.]

ALCHEMY was originally the pretended art of making gold and silver; but another and subsequent object of alchemy was the preparation of a universal medicine. Those alchemists who were supposed to be skilled in the art were termed *adepts* or *the adepts.*

According to the doctrine of the alchemists all the metals are compounds, the baser of them containing the same constituents as gold, but mixed with various impurities, which being removed, the common metals would assume the properties of gold. The change was to be effected by *lapis philosophorum*, or the philosophers' stone, which is commonly mentioned as a red powder possessing a peculiar smell.

As the philosophers' stone was said to take a great part in the pretended transmutations, Dr. Thomson in his 'History of Chemistry,' has endeavoured to discover its probable character. After quoting a description given by one of the alchemists, he states that this mysterious agent could hardly have been any thing else than an *amalgam of gold;* and 'there is no doubt,' he adds, 'that amalgam of gold, if projected into melted lead or tin, and afterwards cupellated, would leave a portion of gold; all the gold, of course, that existed previously in the amalgam. It might, therefore, have been employed by impostors to persuade the ignorant that it was really the philosophers' stone; but the alchemists, who prepared the amalgam, could not be ignorant that it contained gold.'

It is thought by some that the alchemists did injury to chemistry, by bringing it into disrepute; but Dr. Thomson remarks, that a compensation was given in another way:—'As the alchemists were assiduous workmen—as they mixed all the metals, salts, &c., with which they were acquainted, in various ways with each other, and subjected such mixtures to the action of heat in close vessels, their labours were occasionally repaid by the discovery of new substances, possessed of much greater activity than any with which they were previously acquainted . . . . . Thus the alchemists, by their absurd pursuits, gradually formed a collection of facts, which led ultimately to the establishment of scientific chemistry.'

ALCOHOL, is the chemical name, (probably derived from the Arabic), for *ardent spirit.* Alcohol is the intoxicating principle of beer, wine, and fermented liquors in general; and when they are subjected to distillation, the alcohol and a considerable quantity of water are vaporized and condensed together. The distilled products have different names and properties according to the substances yielding them.

It is explained under FERMENTATION, that when that process is going on, a compound of carbon, hydrogen, and oxygen, previously existing in the form of *sugar*, is decomposed, and out of it are formed two other compounds,—*alcohol* and *carbonic acid.* It is in this way that alcohol is obtained for use. The alcohol of commerce is, however, always mixed with water, on account of the great affinity between them; and it is a difficult chemical process to produce absolute or pure alcohol.

Alcohol, in its absolute or anhydrous state (free from water), is a limpid, colourless liquid, of an agreeable smell, and a hot pungent taste. It is composed of carbon, hydrogen, and oxygen. Its specific gravity is 0·791 at 68° F., or 0·7947 at 59° F. It has never been frozen, although exposed to a temperature 91° below zero, or 123° below the freezing point of water. It is extremely volatile, producing considerable cold during evaporation; the degree of cold is proportional to its purity. Heat expands alcohol in a greater degree than it does water, for 100,000 volumes become 104,168 by being heated from 32° to 100°; whereas an equal bulk of water heated to the same degree is increased only to 100,908. Under the average atmospheric pressure alcohol boils at about 173°, but in the vacuum of the air-pump, ebullition occurs at 60° and even below it. Alcohol, and the vapour arising from it, are extremely inflammable; it burns with a lambent flame, the colour of which depends upon the strength of the alcohol; the blue tint prevails when it is strong, and the yellow when weak. Although the flame of alcohol yields but little light, its heat is intense; it burns without any smoke. There are several substances which communicate colour to the flame of alcohol: boracic acid and salts of copper impart green, barytic salts yellow, and the salts of strontia an intense and beautiful red colour. These properties are made available in pyrotechny or fire-works.

Alcohol combines in definite proportions with chloride of calcium, nitrate of magnesia, and other salts, with which it forms *alcoates*. It dissolves resins, essential oils, camphor, sugar, soap, and numerous acids, with readiness; it also readily dissolves ammoniacal gas. As alcohol remains fluid at the lowest temperatures, it is advantageously employed in filling thermometer tubes, and in experiments on artificial cold; its antiseptic properties are great, and hence its use in preserving anatomical preparations; on account of its ready inflammability, the purity, and the intense heat of its flame, it is conveniently, but not economically employed in chemical lamps, usually termed *spirit lamps*. There are many other useful purposes to which this remarkable liquid is applied; but its chief employment is in the form of beverages.

ALCOHOLIC DRINKS. The number of alcoholic drinks is surprisingly large and varied. The following are the principal:—*Agua Ardiente*, made in Mexico, from the fermented juice of the Agave; *Arack* or *Arrack*, made in India from the juice of the palm and from rice; *Araka*, made in Tartary, from fermented mare's milk; *Araki*, made in Egypt from dates; *Arika*, made in Tartary and in Iceland, from fermented cow's milk; *Brandy*, made in nearly all wine countries from wine and from fruits; *Geneva* or *Holland*, made in Holland from malted barley or rye, rectified on juniper berries; *Gin*, made in England from malted barley, rye, or potatoes, and rectified with turpentine; *Goldwasser*, made at Dantzic from various kinds of corn, and rectified with spices; *Kirschwasser*, made in Switzerland from the Machaleb cherry; *Lau*, made at Siam from rice; *Maraschino*, made in Dalmatia from the Macarska cherry; *Mahwah Arrack*, made in India from the flowers of the Madhuca tree; *Rum*, made in the West Indies and South America from cane sugar, and molasses; *Rakia*, made in Dalmatia from the husks of grapes, mixed with aromatics; *Rossolio*, made at Dantzic from a compound of brandy with certain plants; *Sekis-Kayavodka* made at Scio from fruit and lees of wine; *Slatkaia-trava*, made at Kamschatka from a sweet grass; *Show-choo*, made in China from the lees of rice wine; *Trosta*, made in the Rhemish provinces from the husks of grapes fermented with barley and rye; *Tuba*, made in the Philippine Islands from palm-wine; *Vino Mercsel*, made in Mexico by distilling the fermented juice of the Agave; *Whiskey*, made in Scotland and Ireland from raw and malted grain, and in the south of France from sloes.

However different the above alcoholic beverages may be, they all have a common resemblance in these particulars:—they all consist chiefly of dilute spirit or alcohol; they all contain portions of essential oils, or colouring matter, or extractive matter; they all derive their distinctive character from the nature of these added substances; and they may all be made to yield pure alcohol by re-distillation and rectification.

Numerous as they are, these drinks are wholly distinct from the various rich and luscious CORDIALS and LIQUEURS, of which the reader will find a brief account in subsequent articles.

ALCOHOMETER. The rigorous proceedings of the Excise in collecting the duty on English spirits, render the use of several instruments necessary. One of these is the *Alcohometer*, a sort of hydrometer fitted to ascertain the quantity of pure alcohol in any given mixture of spirit and water, for absolutely pure alcohol never comes before the notice of the public generally; it is always combined more or less with water. Various means have been adopted to test the strength of alcohol—finding the temperature of the vapour produced, determining the temperature produced by admixture with water, or ascertaining the degree of volatility; but the mode which has been found best in practice is by determining the specific gravity, which becomes greater and greater as there is more and more water mixed with the spirit: in other words, a pint of spirit and water is *heavier* than a pint of pure spirit. The Excise charge duty, not on the quantity of liquor manufactured by distillation, but on the quantity of pure spirit contained; and this quantity is determined by the alcohometer or hydrometer.

ALDER. [ALNUS.]

ALDERNEY, or AURIGNY, one of the islands in the English Channel, lying in the bay of Avranches, near the coast of Normandy. The soil is sandy, gritty, and gravelly round the coast, but in the valleys it is very fertile, producing excellent corn and potatoes. In the meadows they grow rye-grass and clover, which give excellent milk and butter. The grass lands occupy about one-third of the area of the island. The land is generally elevated, but consists both of high and low tracts; a good supply of excellent water is procured in every part of the island. The Alderney cows maintain their reputation: they are easily distinguished from those of the neighbouring islands by being remarkably small, and straight in the back.

ALE. The distinction between ale and beer, the processes of manufacture, and the arrangements of the great London breweries, are described under BREWERIES AND BREWING.

ALEMBIC, a chemical apparatus used in distillation. It consists of a *body*, *cucurbit*, or *matrass*, to contain the fluid to be distilled; a *head*, or *capital*, fixed above it to receive and condense the vapour which rises on the application of heat to the cucurbit; and a pipe descending from the head to a *receiver*, or vessel prepared to receive the condensed product of distillation, which in its passage from the head to the receiver, is frequently passed through a *worm* or serpentine pipe immersed in cold water as a refrigeratory. Alembics or stills are made of both glass and metal, the several parts being fitted together with ground or luted joints, and of various forms according to the purpose for which they are employed. They are of great use in manufacturing chemistry.

ALEPPO. [HALEB.]

ALEUROMETER. One of the novelties of 1849 was a contrivance called an Aleurometer, invented by M. Boland, a Paris baker, for ascertaining the panifiable or bread-making qualities of wheaten flour. This determination depends upon the expansion of the gluten contained in a given quantity of flour, when freed from its starch. A ball of gluten being placed in a cylinder to which a piston is fitted, the apparatus is exposed to a temperature of 150°; and as the gluten dilates, its degree of dilatation is marked by the piston rod. The greater the dilatation, the better is the flour fitted for making bread.

ALEUTIAN ISLANDS, situated in the North Pacific Ocean, between Cape Alaska in North America, and the peninsula of Kamtchatka in Asia, are one of the centres of the fur-trade. In 1785 a commercial establishment was formed there, for the prosecution of this trade; and in 1799 this company received great aid and protection from the Russian government, which has ever since continued. The fur animals which the islands yield are bears, beavers, ermines, otters, foxes, and seals. Almost the only occupations of the inhabitants are fishing and hunting, and the preparation of implements necessary for the prosecution of those pursuits. In fishing they make use of a species of canoe, which they call a *baidar*, and which consists of a skeleton of wood, over which a covering of seal skins is extended. Thus constructed, these canoes are so extremely light that they may be carried about by one person without difficulty. Domestic occupations, such as making clothes, and even the covering of canoes, are performed by the women, who likewise make mats, baskets, and other useful articles of straw.

The Aleutian Islands have been recommended by Lieut. Maury as a *coaling* station, on the route of the Pacific Steamers from California to China, planned on his proposed *Great Circle* system.

ALEXA'NDRIA, called *Iskanderieh* by the Arabs, the only seaport of Egypt, stands on an artificial neck of land which joins the continent to the ancient island of Pharos. It has two ports. The old port on the west side of the town, is at the extremity of an extensive roadstead; there are three passages into this roadstead, the deepest of which will admit frigates, and probably vessels of the line. The new port, which is on the east side of the town, is more exposed and shallower than the old port. The fort of Pharos, which is also a light-house, is connected with the island of Pharos by an artificial dyke, made in part of antient granite columns laid transversely.

Alexandria is the chief commercial town of Egypt. All the products intended for foreign export are conveyed by the Nile and Mahmoudieh Canal to Alexandria for shipment. The Mahmoudieh Canal, which was restored and completed by Mohammed Ali, in 1819, joins the Nile at Atfeh, 40 miles from Alexandria. Alexandria has become an important station in the line of communication with the East Indies, and its importance in this respect is annually increasing. Steamboats from England, Marseille, Trieste, and Constantinople, sail to and from Alexandria regularly, and goods and passengers, as well as mails, pass by the Mahmoudieh Canal and the Nile to Cairo, thence across the desert to Suez, then by the Red Sea and Arabian Sea to Bombay; and so from Bombay by the same route back again.

It is an instructive example of the changes which mark the history of commerce, that this same city of Alexandria, which is now growing in trading importance every year, was a great centre of commerce more than 2,000 years ago; while in a great part of the intervening period it sank to a position of insignificance. Humboldt, in his *Cosmos*, says:—"Under Ptolemæus Philadelphus, scarcely half a century after the death of Alexander the Great, and even before the first Punic war had shaken the aristocratic republic of the Carthagenians, Alexandria was the greatest commercial port in the world, forming the nearest and most commodious route from the basin of the Mediterranean to the south-eastern parts of Africa, Arabia, and India. The Ptolemies availed themselves with unprecedented success of the advantages held out to them by a route which nature had marked, as it were, for a means of universal intercourse with the rest of the world by the direction of the Arabian Gulf, and whose importance cannot even now be duly appreciated until the savage violence of eastern nations, and the injurious jealousies of western powers shall simultaneously diminish."

ALGÆ is the name given by botanists to the tribe of plants which comprehends the sea-weeds, lavers, and fresh-water submersed species of similar habits. Some of them are only visible to the naked eye when they are collected in heaps; others grow together in the beds of the ocean, and when they rise to the surface form floating banks of such extent as to impede the course of ships. Nearly all the useful species, and those of large dimensions, are to be found among the jointless varieties. All the kinds that are consumed in the important manufacture of kelp [Kelp]; the eatable sorts, which, in the state of birds'-nests, are collected in the islands of the Indian Archipelago and sold at a high price to the Chinese; those which we consume as lava; the species that afford vegetable glue; all those from which the elementary substance called iodine is obtained; and finally the principal part of what our farmers use for manure, belong to the great tribe of *jointless Algæ*, of which 55 genera and about 160 species are known as natives of the coasts or ditches of Great Britain. The *jointed Algæ*, or *confervæ*, and the *disjointed Algæ*, are of less importance in medicine and the arts.

ALGAROTTI, FRANCESCO, a popular French writer of the last century, who had the merit of rendering science and literature fashionable amongst the upper classes of his age, is mentioned here as the author of a calculation often repeated which is a forcible illustration of the value conferred upon a raw material by industrial skill. A pound of iron, he says, cost five sous. This pound of iron is converted into steel; and this steel forms the material of the balance-spring of a watch. Each spring weighs the tenth part of a grain. Allowing for waste, the pound of iron may be fabricated into eighty thousand watch springs. Such a spring is worth eighteen francs; and thus, a material originally worth five sous, acquires a value of one million four hundred and forty thousand francs. The calculation may appear exaggerated; but the principle is unquestionable.

ALGAROVILLA is a substance which was first analysed a few years ago by Dr. Ure. It is produced from a tree which grows in Chili and other parts of South America; and consists of pods bruised and agglutinated with the extractive exudation of the seeds and husks. It contains a good deal of tannin, and may be used for tanning leather; it may be employed as the basis for a very good black ink; and it gives a brilliant yellow dye to cloth, prepared in a particular way for its application.

ALGIERS, frequently called, since its occupation by the French, *Algeria*, or *Algérie*, is better known to English readers as one of the Barbary states. It is situated on the African coast of the Mediterranean, between Tunis on the east, and Marocco on the west. It is gradually losing its Moorish character, and becoming Frenchified; though the Arabs on the southern border are as little disposed as ever to assume European customs. In the twenty years during which the French have possessed this territory (1830-1850) they have had many a struggle to maintain their position.

The fertility for which this country was renowned in ancient times still continues; in the valleys, which are watered by streams, vegetation is extremely luxuriant. The mould is of a very dark colour; in some places it is reddish, and impregnated with nitre or salt. The hills are covered with fruit trees of every kind, and the fruit is generally exquisite. A species of the lotus is found here, the fruit of which is eaten. The palm is indigenous, but the date comes from the southern side of the Atlas. Few timber trees are to be seen except a species of oak, the *quercus ballota*, which bears a very nutritive kind of acorn. The mountains near Bujeiah used to supply the dockyard of Algiers with timber. There are many species of the cypress and chestnut trees. There are also very extensive plantations of the *nessri* or white roses; these flowers are much larger than those of Europe, and yield the essence known by the name of attar of roses. The sugar-cane grows in this country; and a species of it called Soleyman rises to a great height, and gives more sugar than any other species known. The *indigofera glauca* thrives also. The grain sown is wheat, barley, Indian corn, millet, doura, and also rice.

The Kabyles, who form half the native population, are an industrious race in regard to agriculture, mining, and manufactures generally. They make guns, ploughs, and many coarse utensils, which they sell to the Arabs and Moors; they know how to temper steel, and also make sabres and knives of a tolerable quality. They manufacture gunpowder for their own use, but they never sell any of it. Common woollen and linen stuffs, olive oil, and soap made from soda and oil, are among their manufactures. The furniture of their huts is very simple; a few sheepskins or mats spread on the ground, or on a wooden platform in a corner, serve them as beds; their *hykes*, which resemble in shape the plaid of the Highlanders, and their *boornooses* or cloaks with hoods, which constitute their dress by day, serve them as blankets at night; a few baskets, earthen dishes, pots, and jars, for their milk and honey; they keep their grain and fruit in large vats made of clay baked in the sun, or bury them in holes under ground. The Arabs, Turks, and Moors, are similar in their industrial pursuits to those tribes in other countries.

In his address to the manufacturers of France, as to the articles desirable to send to the Exhibition of 1851, M. Charles Dupin enumerates several of the products of Algeria: wools; fruits; cheap oils, fit for manufacturing purposes; cork; woods, so richly coloured, and of such varied shades, for cabinet work; a material for weaving obtained from the fibres of bark or of reeds, the productions made from which are fitted for summer apartments.

ALGO'A BAY is one of those spots in Cape Colony which, by receiving emigrants from Europe, have laid the foundation for commercial intercourse between England and the semi-civilized nations of the south.

ALHAMBRA, an ancient castle and palace of the Mohammedan kings of Granada, is one of the storehouses for examples of the *Arabesque* species of ornament from time to time adopted in modern decorative art. In Mr. Owen Jones's splendid work on the Alhambra, we see how intricate are the patterns and how brilliant the colours of the decorations with which the walls are adorned. A brief account of the existing state of the building may not be misplaced.

The Alhambra is situated on a hill, which runs out to the east of the town of Granada It is surrounded by a strong wall, flanked by square towers, and enclosing an area of 2500 feet in length, and 650 in breadth. The walls follow all the windings of the mountain, and are constructed of 'tapia,' an artificial concrete, consisting of pebbles, rubble, and lime, put moist into a wooden frame. When the mortar was set, the frame was removed, and the portions were used successively in building the walls, which grew harder by time. The colour is reddish, and hence the name 'al-hamra,' 'the red.'

The exterior appearance of the Alhambra is simple and severe, and gives no indication of the gorgeous beauty which once distinguished the interior. The Torre de Justicia, so called because justice was dispensed there after the manner of the East, is a square tower, with a double entrance-gate, the horse-shoe arch in front rising to half the height of the tower. Having passed through the double entrance gates, a narrow passage conducts to the Plaza de los Algibes, or 'Court of the Cisterns,' which are two, the largest 102 feet long and 56 feet wide, arched over, and enclosed by a wall six feet thick. On the east side of this Plaza is the Alcabaza, which is a palace built for Charles V. in the Cinquecento style, by the architect Alonso Berreguete. On the north is a very simple and unostentatious entrance to the Mesuar, or common bathing-court, 150 feet in length and 56 in width. It is paved with white marble, and the walls covered with arabesques of admirable workmanship. In the midst of this court is a basin bordered with flowers. At the lower end of the Mesuar is an archway leading to the Patio de los Leones, or 'Court of the Lions.' It is open to the sky, measures 100 feet by 60, and is paved with white marble. In the centre of it is a large basin of alabaster, of twelve sides, resting on the backs of twelve lions, rudely carved. Over this basin a smaller one rises, from which a large body of water spouts into the air, and falling from one basin into the other is sent forth through the mouths of the lions. This court is surrounded by a gallery supported by above 100 slender and elegant columns, 9 feet high, and 8½ inches in diameter. These columns are very irregularly placed; sometimes they are single, and sometimes in groups of two or three. The walls, up to the height of fifteen feet from the ground, are covered with blue and yellow mosaic tilings. The columns and ceiling of the gallery are beautifully ornamented with arabesques and fret-work in the most exquisite taste. Around the upper face of the Fountain of the Lions are some Arabic verses, which describe, in a style of oriental hyperbole, the wonders and the beauty of the fountain. On each end of the court projects a portico, which is also supported by slender marble columns.

On the left side of the Court of the Lions is the Sala de los Abencerrages, and opposite to the Sala de los Abencerrages, on the other side of the Court of the Lions, is the Sala de las dos Hermanas, or 'Hall of the Two Sisters,' so called from two huge flags of white marble, without a flaw or stain, which are in the pavement. On the upper end of the Mesuar stands the magnificent Tower of Comares. This massive tower rises above the rest of the building, and overhangs a deep ravine.

The Sala de los Ambajadores, which occupies the whole of the interior of the Tower of Comares, still preserves traces of its past splendour. The walls are richly stuccoed and ornamented with arabesques of exquisite workmanship. The ceiling is of cedar-wood, inlaid with ivory, silver, and mother of pearl. The three sides of the hall are full of windows, formed in the immense thickness of the wall, which thus allow a free circulation to the air, and admit a faint light which produces a surprising effect. In the same manner all the halls of the Alhambra are lighted and ventilated. To the east of the Sala de Comares is the Tocador de la Reina, or Queen's Dressing-room, and near it is the Garden of Lindaraja, with its alabaster fountain, and groves of roses, myrtles, and orange-trees.

When we examine the halls of the Alhambra, we are no less surprised at the elegance of their construction and the beauty of their ornaments than at the durability of a work of such a delicate nature; the blue, the carmine, and the gold still preserve all their brilliancy and freshness; the slender columns and apparently fragile filagree work have stood the vicissitudes of five centuries.

ALICANTE, a modern province of Spain, formed of the southern portion of the kingdom of Valencia and a small part of Murcia, is noted for its fertility and industry. The inhabitants are very industrious, aod cultivate the land with great care: irrigation is much and successfully employed. Wheat is little cultivated, but rice, oranges, citrons, figs, almonds, and dates, are grown in large quantities; barilla, the sugar-cane, the cotton tree, and all equinoctial plants flourish. The quantity of wine produced is considerable, and of the best quality, especially that grown in the environs of the city of Alicante. Linen, broadcloth, soap, paper, and worsted-yarn are manufactured: there are several brandy distilleries in the province. Great attention is paid to the rearing of silk-worms and bees, and the tunny, anchovy, and other fisheries on the coast are very productive. Nearly 1000 ships, Spanish and foreign, enter the harbour of Alicante town yearly. The greater part of its foreign trade consists of imports of linen from France and Genoa, tobacco from the United States of America, and cod-fish from Newfoundland; its exports are, barilla and almonds to England and Ireland, and wine to Brazil and the coast of Barbary. A considerable quantity of wine is also shipped to the port of Cette, in Languedoc, whence it is sent to Bordeaux, to be mixed with the inferior Medoc wines. Alicante likewise exports oil, olives, brandy, and soap: the quality of the last-mentioned article is much esteemed. The communications between the town and the contiguous country are for the most part kept up by means of small coasting vessels of from 20 to 70 tons burthen, the roads being so exceedingly bad, that such goods as are sent by land must be conveyed on the backs of mules and asses. All cotton manufactures being prohibited, a great contraband trade is carried on from Gibraltar, Algiers, and Oran, chiefly by Spanish fishing-boats

ALIQUOT PART. The determination of aliquot parts of weights or of sums of money is of so much use in commerce that it may be briefly explained here. One number or fraction is said to be an aliquot part of a second number or fraction when the first is contained an exact number of times in the second. Thus, 6, 3, 4, 2, 1½, ½ ⅓, &c., are all aliquot parts of 12, being contained in it respectively 2, 4, 3, 6, 8, 24, 36, &c. times. The word is principally used in the arithmetical rule called *practice*, and the convenience of using it is as follows. If we want to know how much 30½ yards cost at 1*l.* 15*s.* 6*d.* a yard, the direct process of common arithmetic would be to turn 30½ yards into half yards, giving 61, and 1*l.* 15*s.* 6*d.* into sixpences, giving 71. Then multiplying 61 by 71, and dividing the product by 2, we have the number of sixpences which 30½ yards cost, which must then be reduced into pounds, shillings, and pence. But if we observe that 1*l.* 15*s.* 6*d.* is made up of 1*l.*, 10*s.* the half of one pound, 5*s.* the half of 10*s.*, and 6*d.* the tenth of 5*s.*, we can proceed as follows:

	£	*s.*	*d.*		£	*s.*	*d.*
30½ yards at	1	0	0	per yard cost	30	10	0
„	0	10	0	„	15	5	0
„	0	5	0	„	7	12	6
„	0	0	6	„	0	15	3
„	1	15	6	„	54	2	9

in which each line is derived from the preceding by simple division, on the obvious principle that at 6*d.* a yard we give the tenth part of what we give at 5*s.* a yard, and so on.

ALIZARIN. [Madder.]

A'LKALI is a word compounded of the Arabic article *al* and *kali*, the name of the plant by burning which a saline mass is obtained containing the alkali in question; and in this term are comprehended various other bodies possessing similar properties. The alkalies are numerous, and they are all compound substances; they do not result, however, from the action of any specific or alkalizing principle, being very variously constituted. All exist in nature, and some may be artificially formed. The alkalies may be divided into three classes:—

1st. *Ammonia*, existing in the animal fluids, and composed of two gaseous bodies, viz., hydrogen and azote. As it readily evaporates it was formerly called the *volatile alkali.*

2nd. *Compounds of certain metals and oxygen*, among which are potash and soda, which, though long known as the *fixed alkalies*, and usually obtained from the ashes of plants, were discovered by Davy to be metallic oxides. This class also comprehends the alkaline oxides or earths, lime, magnesia, &c. No metal yields two alkalies by different degrees of oxidizement; nor does any one become an alkali and an acid.

3rd. The *vegeto-alkalies*, produced in plants during vegetation. They are, as far as has been ascertained, quaternary compounds of oxygen, hydrogen, carbon, and azote. This class includes *quina*, an active medicinal principle of chinchona or bark, and *morphia*, one of the narcotic principles of opium, &c., [ALKALOIDS.]

The chemical and distinguishing properties of the alkalies are, that their aqueous solutions turn vegetable blues green, and vegetable yellows reddish-brown; and hence infusion of red cabbage and infusion of turmeric, or paper stained with them, are used as tests of the presence of an alkali. The alkalies restore the colour of vegetable blues which have been reddened by acids, and, on the other hand, the acids restore vegetable colours which have been altered by the alkalies. The alkalies have great affinity for and readily combine with acids, forming *salts* and the power of both in altering vegetable colours is generally destroyed. The alkalies are separated at the negative pole of the voltaic trough. In odour, taste, molecular form, and uses in the arts, the alkalies differ considerably. The salts formed with alkalies are apt to *effloresce*, and resolve the crystals into the state of powder, or to absorb water from the air, and *deliquesce*, or become liquid. The alkalies possess a power of rendering albumen soluble: unboiled white of egg is an albuminate of soda. The albumen of the blood is rendered more fluid by alkalies; hence in excess they impair the plastic power of that fluid. The chief practical uses of the alkalies are noticed under the names of the principal varieties, AMMONIA, POTASH, SODA, &c.

ALKALIMETER. Like as acids and alcohols call for the use of acidimeters and alcohometers to measure their strength, so do alkalies require the aid of analagous instruments, which may fittingly be called alkalimeters. Chemists are aware of many methods of effecting this; and neat instruments have been devised for the purpose. The German soap boilers adopt a somewhat clumsy mode of determining the strength of the alkali which they employ; they pour a quart of water on a pound of alkali, then put in a piece of Dutch soap, and add water until the soap sinks: the more water required to bring about this result, the stronger is the alkali supposed to be. But in the land of Liebig such a rough method is not likely to continue: it is being superseded by more scientific processes.

ALKALOIDS, substances which modern chemistry has discovered, are termed sometimes *vegetable alkalies* as hitherto found only in vegetables, and sometimes *organic alkalies*, from requiring a vital power to effect their formation; but the name given to them above is the most appropriate. They possess alkaline properties in the lowest degree, and are either tasteless or have a bitter acrid taste, existing generally in a solid, mostly crystalline form; some, however, are amorphous (Aconitinæ), occasionally in a liquid state (Conia and Nicotina), the latter very volatile, and readily undergoing decomposition, with an evolution of ammonia, at a moderate temperature. The point in which they differ most from the common alkalies (except Ammonia) is in having nitrogen in their composition, one of them (Caffeina) being perhaps the most highly nitrogenized compound known. Sometimes one only exists in a plant, sometimes several in the same plant, as in opium. Generally they are combined with an acid; most frequently it is a peculiar acid. Many of them are with difficulty soluble in water, more so in alcohol; they seldom completely neutralize acids, but the salts which they form are more soluble than the bases; hence various of their salts are used in medicine in preference to the primitive article. The alkaloids are less extensively used in the manufacturing arts than in medicine.

ALKERMES is the name of a favourite cordial, made in some of the northern countries of Europe. It is made from bay leaves, mace, nutmegs, cinnamon, cloves, brandy, syrup of kermes, and orange-flower water.

The first six ingredients are distilled, and the last two are employed to give flavour.

ALLANTOIN, ALLANTOIC ACID, exists in the allantoic liquid of cows, and has the form of brilliant colourless crystals derived from the rhoimboid, with a vitreous appearance. It has, we believe, not yet acquired value in the arts.

ALLIUM is the botanical name of the genus of plants which includes the onion, chive, garlic, shallot, and leek. The *allium cepa*, or common onion, has many varieties; the most remarkable are the blood red, which is the most pungent; the Strasburg, which is the hardiest; the silver-skinned, which is the smallest, and the most fitted for pickling; and the Portugal and Tripoli, which are the largest and the most delicate. The *allium fistulosum*, the Welsh onion, is a native of Siberia, and is cultivated chiefly for the purpose of being sold in the markets when very young, at which time its flavour is delicate. The *allium ascalonicum*, the shallot, a native of Asia Minor, is in many respects similar to the chive. Garlic and leek are other well-known species of the genus.

MM. Fourcroy and Vauquelin have found that the common onion is composed, 1, of a white, acrid, volatile oil, holding in solution sulphur which renders it fetid; 2, of a vegeto-animal matter analogous to gluten; 3, of a good deal of uncrystallizable sugar; of a great quantity of mucilage, resembling gum arabic; 5, of phosphoric acid, either free or combined with lime, acetic acid, and a little citrate of lime; and 6, of vegetable fibre. It is to the volatile oil that the irritating properties of the onion are supposed to be owing, and they are consequently dissipated by heat.

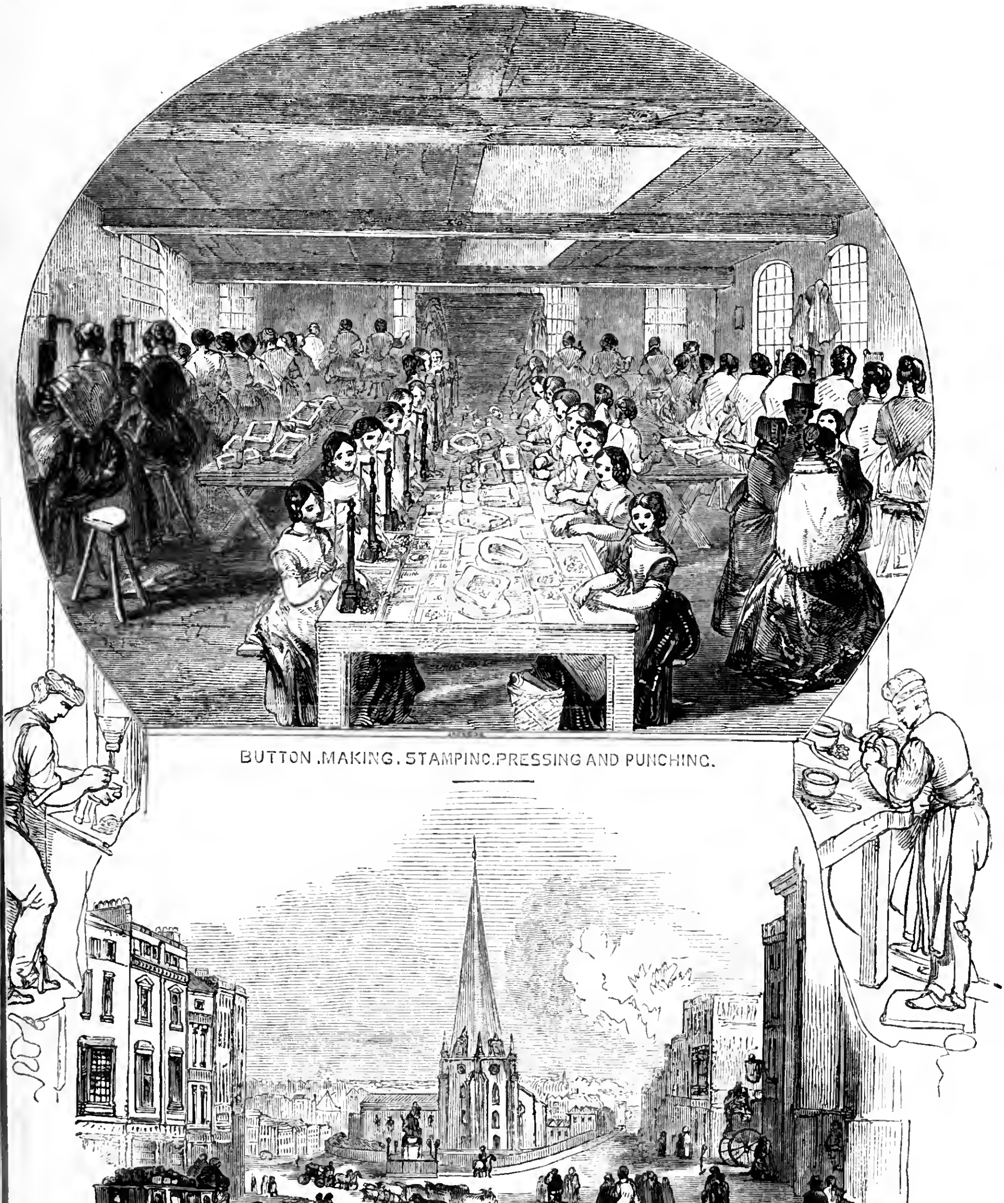
ALLOA, a Scottish sea-port town, in the county of Clackmannan, is a place of considerable manufacturing and commercial importance. It contains large distilleries, several breweries, where ale is made which has long been in high repute, woollen manufactories (chiefly for the blanket and shawl trade), glass-works, corn and flour mills, gas works, and a great iron-foundry, chiefly for the making of steam-engines. The Devon iron-works, near the town, contribute largely to the trade of the port. Bricks, tiles, and other earthenware, copper goods, (especially distillers' apparatus), leather, tobacco, and snuff, are also extensively manufactured. The salmon fishery is carried on with considerable spirit. Alloa possesses a commodious harbour, with a depth of water of 16 feet at neap-tides, and from 22 feet to 24 feet at spring tides. Its vessels sail to every quarter of the globe; and their number and burthen was registered in 1848 at 108 vessels of 17,100 tons, including three steamers. The coasting trade is also very extensive: the export of coals alone amounting to 60,000 tons annually. The imports consist of corn, wool, wine, tea, timber, hemp, oak bark, &c.; the exports are coals, and the many industrial products of the town and neighbourhood. There is a large dry dock in the harbour; and capacious steamers work at the ferry over the Forth.

ALLOWANCE, in commerce, a deduction from the gross weight of goods, agreed on between merchants, according to the customs of particular countries and ports, the chief of which is known by the name of TARE.

ALLOXAN, ALLOXANIC ACID, and ALLOXANTIN, are three substances which organic analysis has recently placed within the domain of chemistry. The first and third are crystalline, the second is a liquid. None of them are yet, we believe, employed in the arts.

ALLOY, either a natural or artificial compound of two or more metals, except when mercury is one of them, in which case the mixture is called an *amalgam*. Native or natural alloys, considered as such, are not useful bodies, the only exception, if indeed it may be so reckoned, is the alloy of iron and nickel, constituting *meteoric iron*, of which the knives of the Esquimaux appear to be made; but artificial alloys are of the highest importance, since by uniting different metals compounds are formed which possess a combination of qualities not occurring in any one metal. Gold, silver, tin, antimony, and bismuth are generally alloyed; the first three on account of their softness, and the two latter because they are extremely brittle. Gold and silver are hardened by alloying with copper; copper is hardened by zinc, &c.

The formation of alloys appears to depend upon the chemical affinity of the metals for each other; and in some instances it seems to be wanting, for no combination occurs. Various facts may be assigned for supposing the combination to be the result of chemical affinity. M. Boussingault analysed six different native alloys of gold and silver, and found in all cases that the metals were combined in definite proportions. The change of properties which metals undergo by combining, furnishes strong evidence of its arising from chemical affinity and action; thus, with respect to colour, copper, a reddish metal, by union with zinc, which is a white one, gives the well-known yellow alloy, brass. The fusing point of a mixed metal is never the mean of the temperature at which its constituents melt; and it is generally lower than that of the most fusible metal of the alloy.



BUTTON MAKING. STAMPING, PRESSING AND PUNCHING.

THE BULL RING BIRMINGHAM.

KNIGHTS' CYCLOPÆDIA OF THE Industry of all Nations

No. 4.

All alloys formed of brittle metals are brittle; those made with ductile metals are in some cases ductile, in others brittle; when the proportions are nearly equal, there are as many alloys which are brittle as ductile; but when one of the metals is in excess, they are most commonly ductile. In combining ductile and brittle metals, the compounds are brittle, if the brittle metal exceed, or nearly equal, the proportion of the ductile one; but when the ductile metal greatly exceeds the brittle one, the alloys are usually ductile. The density of alloys sometimes exceeds, and in other cases is less than, that which would result from calculation.

Not only are the properties of metals altered by combination, but different proportions of the same metals produce very different alloys. Thus, by combining ninety parts of copper with ten parts of tin, an alloy is obtained of greater density than the mean of the metals, and it is also harder and more fusible than the copper; it is slightly malleable when slowly cooled, but on the contrary, when heated to redness, and plunged into cold water, it is very malleable: this compound is known by the name of *bronze*. If eighty parts of copper be combined with twenty parts of tin, the compound is the extremely sonorous one called *bell-metal;* an alloy consisting of two-thirds copper and one third tin, is susceptible of a very fine polish, and is used as *speculum metal.*

It is curious to observe in these alloys, that in bronze the density and hardness of the denser and harder metal are increased by combining with a lighter and softer one; while, as might be expected, the fusibility of the more refractory metal is increased by uniting with a more fusible one. In bell-metal the copper becomes more sonorous by combination with a metal which is less so: these changes are clear indications of chemical action.

The principal alloys employed in manufactures are the following:—Arsenic and copper make *packfong;* tin and lead make *solder* and *common pewter;* tin, antimony, copper, and bismuth make *best pewter* and *Britannia metal;* tin, lead, and bismuth make *fusible metal;* tin and copper, in various proportions, make *bronze*, *speculum metal*, *bell-metal*, and *gun-metal;* copper and zinc, in different proportions, make *brass* and *Dutch gold;* copper, zinc, nickel, and iron make *German silver;* silver and copper make *standard silver;* gold, silver, and copper make *standard gold.* In many of these alloys, such as the last two, the quantity of one of the metals is extremely small, but still it is sufficient to give a distinct property to the alloy.

Dr. Weiger, of Vienna, proposed in 1845 many modes of making fine alloys, chiefly for the use of dentists. Gold, silver, platina, and palladium are the metals employed; and these are taken—two or three together—in such proportions as to form eight different alloys: platinum being in every case one of the metals. In making alloys for such delicate uses as those of the dentist, the purity of the single metals is as important as the combining of the whole; and Dr. Weiger details processes in respect to both these qualities.

ALLU'VIUM, or ALLUVIAL DEPOSITS, a name given to those accumulations of sand, earth, and loose stones or gravel brought down by rivers, which, when spread out to any extent, form what is called *alluvial land.* There are three successive stages in the formation of the alluvium: viz. the crumbling of the mineral crust of the earth, by the action of the tides, currents, streams, and atmospheric agency; the transportation of the loosened fragments; and their deposition in the form of alluvium at the bottom of rivers, lakes, æstuaries, and the ocean. Alluvium is important to the arts of life in this way; that when such a deposit is made, it is fitted to become the basis of a rich vegetable soil, by converting into dry land tracts which were before covered with water, but which now form *deltas*, such as those of the Nile, the Ganges, the Rhine, the Mississippi, &c., Alluvial action also breaks down the rigidity of mineral deposits, and renders their wealth more easily attainable; as is exemplified in the gold sands of California, the diamond-washings of Brazil, the stream-tin of Cornwall, &c.

ALMADEN, a town in the Spanish province of La Mancha, about 130 miles from Madrid, is famed for its mines of quicksilver, which have been known for more than 2,000 years. The hill in which the mines are found is 120 feet high; and the cinnabar (ore of mercury) is met with in different parts of the mass. It does not appear that this district is so unhealthy as the quicksilver mines of Idria; for a miner sleeps with safety upon a vein of cinnabar. The galley-slaves, who work in these mines, are not exposed to the hardships that are commonly believed. They only work three hours a day, and do nothing but take out the earth in wheelbarrows. Some feign convulsions, and others fits, to excite the compassion of those who visit the mines. The inhabitants of Almaden work willingly double the time, and receive only half of what every slave costs the government.

The cinnabar occurs in veins which traverse the hill; and pure mercury is also found in crevices of sandstone and slate. For roasting the ore, ovens and other apparatus are provided; the ovens are twelve in number, and are called by the names of the twelve apostles. Each is capable of containing ten tons' weight of stone. The oven is kept burning for three days, and the same time is required to cool.

The celebrated German merchants, Mark and Christopher Fugger, leased the mines in the seventeenth century; but they were afterwards worked by the Spanish government.

ALMOND. The favourite fruit *Amygdalus communis*, or common almond, is a native of Barbary. In this country it is only grown for the sake of its beautiful vernal flowers; but in the countries that have a long and hot summer, it is the fruit for which it is esteemed. This, which is produced in immense quantities, is partly exported into northern countries, and partly pressed for oil, or consumed for various domestic purposes. There are two varieties of it, sweet and bitter. Of the sweet almonds the parts which are officinal are the seeds or kernels. The commercial varieties are numerous, but the most esteemed are the Jordan almonds. Triturated with water, sweet almonds form a grateful sweetish emulsion, which possesses considerable nutritous as well as demulcent properties. Almonds, as an article for the dessert, are nutritive but rather indigestible. *Oil of Almonds* may be obtained from either variety, but is yielded in great abundance by the bitter almond. Almonds which have become rancid yet yield by expression good oil, if a little calcined magnesia be added to the bruised almonds before being subjected to pressure. Almond oil is often adulterated with poppy oil. Bitter almonds are smaller and flatter than the sweet. Those most esteemed come from Provence, those least esteemed from Barbary. They have a very bitter taste, and scarcely any odour, but if rubbed between the fingers with a little water, they emit a peculiarly agreeable odour.

About 21,000 cwts. of almonds, and 6,000 cwts. of bitter almonds were imported in 1848.

ALNUS is the botanical name for the genus of *alder* trees, which comprises many useful species. The common alder, called the *alnus glutinosa*, is an inhabitant of swamps and meadows in all parts of Europe, the north of Africa and Asia, and North America. Next to the charcoal from black dogwood (*Rhamnus frangula*), that supplied by the common alder is of the best quality. The bark is valuable for tanning, and the young shoots for dyeing various colours; the veiny knots of its wood are cut into veneer by cabinet-makers, and its stems, hollowed out, are among the best materials, next to metal, for water-pipes and underground purposes.

ALOE, a genus of succulent plants, the best species of which is the ***Aloe Soccotrina***, a native of the Cape of Good Hope and the Island of Soccotra. Attention to the mode of extracting the juice might render aloes, whencesoever procured, of excellent quality. But from the different plans of collecting and inspissating the juice, results an article which differs considerably in appearance and greatly in value. Aloes is one of the few drugs in which adulteration is not extensively practised further than by substituting the inferior and low-priced kinds for the superior. When carelessly prepared, sand and fragments of leaves and skins are frequently found in the samples. Caballine, or *horse* aloes, has nearly disappeared from commerce, refinement or fashion in veterinary medicine deeming it not fit for horses. Barbadoes aloes comes to this country in the gourds and calabashes into which it is poured when prepared. Each of these weighs from sixty to even eighty pounds.

Few more valuable drugs exist, as is proved by the numerous preparations made either of aloes alone, or with some other articles combined with it. These combinations have various objects in view, some to heighten its powers, others to modify, and some to get rid of certain well-founded objections to its effects. The use of aloes is almost entirely confined to medicine.

ALOPECU'RUS. [GRASS.]

ALPA'CA, or PACO, is the wool of the *llama*, or goat of Peru and Chili. The introduction of alpaca wool in manufactures has attracted considerable attention, and the question of naturalizing the alpaca in this country, in Germany, and in Australia, is also an object of much interest. The wool of the alpaca is superior to English wool in length, softness, and pliability. The fleece averages from 10 to 12 pounds, while that of our sheep is seldom more than 8 pounds; and while the staple of English wool does not often exceed six inches in length, that of the alpaca varies from eight to twelve inches. The lustrous appearance of the alpaca wool renders it applicable to many of the purposes for which silk is usually employed in textile fabrics; and it is found a useful substitute for Angora wool. The manufacture of plain and figured stuffs from the fleece of the alpaca was commenced at Bradford, in Yorkshire, a number of years ago, and there is a large and increasing use of alpaca wool. In 1844 five different articles were manufactured at Bradford for her Majesty, from the wool of an alpaca which had been kept at Windsor, copies of which articles were exhibited at the Free Trade Bazaar in 1845.

Besides the use of the wool in textile fabrics, the flesh of the alpaca is also wholesome and palatable. The carcase weighs on an average about 180 lbs.

The question of naturalising the alpaca has been taken up with great enthusiasm by a few persons; but very little progress has yet been made in demonstrating its practicability. The alpaca inhabits the mountainous and inhospitable regions of Peru, and is remarkable for its abstemiousness. It thrives on coarse food. Those which have been brought to this country have been confined in parks and richly cultivated lands, and have been treated with too much care and tenderness. Mr. Walton asserts that they will live where our hardiest sheep would starve, and that the wildest parts of Great Britain are best suited to their habits. If the alpaca may be pastured on lands which are now waste and unprofitable, and where the hardiest sheep would starve, the naturalization of the animal would undoubtedly prove a great national benefit; but if this is not the case, it is a question whether a constant demand for the wool as an article of import would not be quite as beneficial.

Alpaca is now used to a very large extent in manufactures—umbrellas, paletôts, and various articles and garments are made of it, as it presents a sort of compound of the qualities of silk and woollen.

ALPS. In a commercial point of view, the Alps are interesting to the extent that they afford practicable passes for carriage roads, across or between their summits. These passes and roads are as follow:—In the *Maritime Alps*, which extend from the Gulf of Genoa to Monte Viso, a distance of about 100 miles, the only carriage-road across is by the Col de Tende, at an elevation of 5887 feet, formed by Napoleon; there are three or four smaller roads practicable for mules. In the *Cottian Alps*, which extend from Monte Viso to Mont Cénis, a distance of about 60 miles, the carriage-road of Mont Genèvre, formed by Napoleon, is the chief pass, leading from the valley of the Durance in France to Susa in Piedmont. In the *Graian Alps*, extending from Mont Cénis to the Col de la Seigne, about 60 miles, is Mont Cénis, one of the best known of the Alpine passes. This pass was only a mule-road till 1803, when Napoleon commenced a magnificent carriage-road, which crosses the chain at a height of 6773 feet. The pass of the Little St. Bernard, which is supposed to be that by which Hannibal entered Italy, crosses the Graian Alps to the Val d'Aosta. In the *Pennine Alps*, extending about 60 miles from Mont Blanc to the Simplon, are Mont Blanc, Monte Rosa, and Mont Cervin, the three loftiest peaks in Europe. On each side of Mont Blanc are cols or passes of the mountains, usually traversed by pedestrians in their tours about Mont Blanc. There are three larger passes, however, viz. the *Great St. Bernard*, with a Hospice at the height of 7963 feet above the level of the sea; the *Cervin*, at a height of 11,096 feet; and the *Simplon*, the pass of which, at an altitude of 6578 feet, is one of Napoleon's most magnificent works. In the *Helvetic or Lepontian Alps*, extending from the Simplon to Mont St. Gothard, a distance of about 60 miles, is the pass of St. Gothard, a valuable carriage-road from Switzerland to Italy, which has a summit level 6890 feet high. In the *Rhætian Alps*, which extend about 80 miles east from St. Gothard, are many good passes for travellers. One is the Mont St. Bernardin, at an elevation of 6700 feet; another the Splugen; another the Maloya, 8130 feet; another the Stelvio, 9174 feet; and another the Brenner, 4660 feet—all of which connect Tyrol and the Grisons on the north with Lombardy on the south. In the *Noric*, *Julian*, and *Carnic* Alps, which bend round from the Tyrol towards the head of the Gulf of Venice, are the high roads from Salzburg to Venice, and from Vienna to Trieste. In these, as in most other parts of the Alpine chains, the neighbouring governments are vying with or rather aiding each other to add to the number of carriage-passes.

The central ranges of the Alps are, in a great measure though not altogether, composed of gneiss, mica slate, talcose slate, and others of the like character. Gneiss may be considered as very abundant: it constitutes the mass of Mont Blanc, and of several other lofty mountains. The mica slates occasionally contain many minerals, among which may be enumerated garnet, staurotide, cyanite, hornblende, tourmaline, and titanite. Other portions of the Alps present newer geological formations, many of which will form a storehouse of materials for manufactures, as soon as man shall have located his industrial establishments in those parts.

The number of mines worked in the Alps is not very considerable, when compared with the great extent of the mountains. A few gold and silver mines are worked, as at the Rathausberg; and others of copper, lead, iron, and anthracite. The iron-mines of Styria, Carinthia, and Carniola, are very productive. The Bleiberg in Carinthia yields some of the best lead in Europe. The quicksilver mines of Idria have been long celebrated. Salt is procured in many parts of the Tyrol and the neighbouring districts.

The vegetation of the Alps differs in many respects from that of the plains beneath. At the foot of the Alps, for instance, are rich vineyards, and wine is one of the staple products of the country; the forests consist of most of the common European trees. But at the low elevation of 1950 feet the vine is no longer capable of existing; at 1000 feet higher sweet chestnuts disappear; 1000 feet farther, and the oak is unable to maintain itself; at the elevation of 4080 feet, less than one-third of the height of Mont Blanc, the birch, as well as almost every other deciduous tree, ceases; the spruce fir alone attains the height of 5900 feet, after which the growth of all trees is arrested, not by perpetual snow, which does not occur for more than 3000 feet higher, but by the peculiar state of the soil and air.

ALSACE, is one of the most important manufacturing provinces in France. It used to consist of two districts, Upper and Lower Alsace, one of which is now included in the Department of Haut Rhin, and the other in that of Bas Rhin. Both districts are watered by the Rhine.

Lower Alsace produces corn of all kinds in quantitymore than enough for the consumption. Wheat is the chief grain crop; spelt wheat is extensively grown in the north; rye also is an important crop; oats is but little grown except on the highlands. Madder and tobacco are objects of careful cultivation in the valley of the Rhine; about 25,000 acres of the best soils are under tobacco culture. Excellent hemp is grown. From cabbages, which are extensively cultivated and grow to an enormous size, a great quantity of *choucroute* or sauerkraut is made for export to Strasbourg and Germany. Among other productions must be named oleaginous seeds, onions, beans, hops, and gentian. Great quantities of large plums for preserving are grown; and also cherries, from which excellent kirschwasser is made. About 11,000,000 gallons of wine are produced annually, one half of which goes to the home consumption: the rest is exported to the right bank of the Rhine. There is a great breadth of meadow land in the department. Horses and cows are very numerous, and of good breed: both oxen and horses are employed in agriculture. The number of sheep is comparatively small. Swine are reared in great numbers; and also geese, the livers of which are used in making the famous Strasbourg pies. The woodlands are very extensive; considerable part of the timber is formed into small rafts, and floated down the Rhine to Mainz, where they are united, so as to constitute enormous rafts from 250 to 300 yards long, and 25 to 30 yards broad, conducted each by 300 or 400 men.

Iron ore is very abundant: 28 mines are worked. Lead, antimony, manganese, and some traces of silver are found. Coal mines are worked. Building stone, plaster of Paris, potters' clay, slates, and asphalte are quarried. Pebbles, admitting of a fine polish, are found in the Rhine. The department contains several mineral springs.

The industrial products are very important and numerous; they comprise fine woollen cloths, linen, calico, sailcloth, cordage, straw hats, playing cards, room paper, hair brushes, horn combs, mineral acids, oils, soap, ivory black, ironmongery, hardware, saw-blades and tools of all kinds, fire-arms, swords, surgical instruments, gloves, buff leather, dressed skins, paper, &c. There are numerous madder mills, paper mills, potteries, bleach works, breweries, tan-yards, cannon foundries, and 27 iron forges and furnaces. These branches of industry are chiefly carried on in the towns of Strasbourg, Bischwiller, Hagenau, Wasselonne, Saverne, Bouxwiller, Schélestadt, Weissembourg, Lauterbourg, &c.

Upper Alsace is situated somewhat farther to the south, or higher up the Rhine. Like the Lower district, it has numerous canals which are employed for floating timber and transporting merchandize. The products are similar to those of Lower Alsace, and more than suffice for the consumption, though formerly this was not the case. The annual vintage yields about 12,760,000 gallons, of which a considerable surplus above the home supply is exported to Switzerland and Germany. A large quantity of kirschwasser is also made. The domestic animals are similar in kind and in number to those of Bas-Rhin; but goats are much more numerous. Even amid the mountains there are some very productive valleys. Cultivation is carried on with great care. The abundant supply of wood in the Vosges Mountains furnishes fuel for the various manufactures of the department. It is floated down the streams which flow into the Ill or the Doubs.

Silver, copper, and lead are found; a great number of iron mines are worked; also mines of antimony, coal, and asphalte; rock-crystal, marble, porphyry, granite, building stone, gypsum, potter's clay, marl, ochre, &c., are quarried. There are mineral springs in several localities.

The industrial products are of the most varied description: this being one of the most active seats of the cotton manufacture in France. The manufactures generally comprise calicoes and printed cottons of all descriptions, shawls, handkerchiefs, hosiery, fine woollen cloths, flaxen and hempen fabrics, ornamental paper, straw hats, chemical products, soap, leather of all kinds, ironmongery, iron wire, clock and watch movements, pottery, &c. There are also numerous cotton, thread, and woollen yarn factories; dye-houses; sugar-refineries; establishments for distilling spirits from pressed grapes, corn, cherries, gentian, potatoes, and carrots; iron furnaces and forges, paper-mills, breweries, tanyards, potteries, and glass works. Colmar, Guebwiller, Mariakirche, Rouffach, Wintzenheim, MÜHLHAUSEN, Belfort, Cernay, Thaun, and Massevaux are the chief towns in which these varied manufactures are carried on.

The chief articles of commerce are the leading industrial products, together with wine, corn, spirits, kirschwasser, steel, bar-iron, iron castings, watch and clock movements, fruit trees, cattle, &c. We may reasonably expect that Alsace will well maintain the reputation of French manufactures in the approaching display of the world's industry.

ALSTON, or ALDSTONE, in Cumberland, is the centre of a district which, though mountainous and sterile, is rich in mineral wealth. It is one of the principal lead districts in England, the produce at present being about 9000 tons per annum. Many of the lead-mines belong to Greenwich Hospital, to which they were given on the forfeiture of the estates of the unfortunate Earl of Derwentwater, who was engaged in the Rebellion of 1745. A little copper is raised in the neighbourhood, and a small per centage of silver is extracted from the lead ore. A branch of the Newcastle and Carlisle Railway is now (1850) being constructed from Haltwhistle to Alston.

ALTAI MOUNTAINS, forming a line of division between Siberia and Tartary, are rich in gold, silver, copper, and lead. The mines containing these metals were worked at some remote period, but by whom or when is not known. They were re-opened by the Russians in the last century, and have been since then extensively worked. The region contains poplars, willows, medlars, privets, whitethorns, and wild roses, on the low banks of the Irtish; and large forests of larch, birch, and other trees, on the slopes of the mountain. The inhabitants use as a substitute for tea the dried leaves of the *Saxifraga crassifolia*. Agriculture is carried on, but not to a great extent, in the valleys. With the exception of mining, the chief occupation of the inhabitants is that of pasturing cattle. The mode in which commercial intercourse is kept up between this remote region and the various countries of Europe and Asia, is noticed under RUSSIA and SIBERIA.

ALTAR-PIECE. We are accustomed in this country to give the name of Altar-piece only to paintings on sacred subjects placed over the altar at churches; but in earlier times the same name was given to small elaborately worked productions in gold and silver, and other metals, connected with the offices of religion. The recent exhibition of Mediæval Art at the rooms of the Society of Arts (1850) contained many such specimens in which much skill was often shewn both by the artist and the artificer. One was an altar-piece of silver, partly gilt, enriched with scrolls and garlands, and enclosing enamels and gems.

ALTIMETER, is the name which the Rev. E. L. Berthon gives to a measuring instrument patented by him in 1850. It is a somewhat complicated contrivance, intended to measure the altitude of the sun, moon, or a star. There are two glass bulbs, one containing mercury and the other spirit, and placed in connexion with each other by vertical and horizontal tubes. A telescope is attached through which the object is viewed. The vertical tubes are graduated; and the heights at which the two fluids adjust themselves in these tubes, when the telescope is directed obliquely upwards, is made to indicate the altitude or angle of elevation of the object viewed, by a particular arrangement of the several parts.

ALTON, in Hampshire, has become quite celebrated for the ale produced there; the breweries are conducted on an extensive scale. There are also paper manufactures; and in the vicinity are fine and prolific hop-grounds. The Farnham branch of the South Western Railway is to be extended to Alton.

ALTO-RILIEVO (high relief), a term which designates that kind of sculpture which is executed on a flat surface, but projects considerably above the ground or plane. The most legitimate use of alto-rilievo is where it is introduced in alternate or occasional compartments to give relief by the boldness of its projections to the uniformity of a large surface. Such are the Metopes among the Elgin Marbles, which, alternately with the triglyphs, ornamented the frieze of the entablature which surmounted the exterior colonnade of the Parthenon. Fifteen of these original Metopes, with one cast, are in the British Museum; they are of unequal execution, but several of them may be referred to as the finest examples extant of alto-rilievo.

A'LTONA, the largest and most populous town in the duchy of Holstein, has extensive trade with France, England, the Mediterranean, and the West Indies. Ship-building is carried on to a considerable extent, and several vessels belonging to Altona are annually employed in the herring and whale fisheries. It enjoys in respect of trade several privileges, which constitute it a free port, and all sects, Jews included, have civil and religious liberty. A railroad connects the town with Kiel, a port on the Baltic. The principal manufactures consist of silk, woollen and cotton goods, tobacco, soap, and vinegar ; there are also glass-houses, distilleries, breweries, and sugar-refineries in the town.

ALUM, is an earthy salt, which occurs in a native state only in small quantities; but it has been long artificially made and extensively employed in various chemical manufactures. Its basis is sulphate of alumina, combined usually with sulphate of potash, but sometimes with sulphate of soda or sulphate of ammonia: when the first alkaline salt enters into its composition, the product is *common* or *potash alum*, the second forms *soda alum*, and the third *ammonia alum*.

At La Tolfa, in Italy, alum is prepared from an alum-stone, which contains all the ingredients mixed with silica. At the alum-works near Whitby, in Yorkshire, alum is produced from alum-slate, the stratum of which is nearly thirty miles in length. Near Glasgow alum is manufactured from *clay slate;* which is obtained from coal mines, and contains a double sulphate of iron and alumina. Alum is also produced in chemical works, by the direct union of the component ingredients.

The alum mine at Hurlet is well worthy of a visit; it possesses many of the striking characteristics of most mines, without being so deep or so dirty as the majority of those underground workings. The land belongs to the Earl of Glasgow, and contains beneath the surface beds of alum, iron, coal, and lime ; and what is very curious is, that the owner leases these different kinds of mineral riches to different parties, even though they may occur in immediate juxta-position ; thus, the Hurlet Alum Company leases the alum deposits, but must not touch the other treasures, even though they occur in the same excavations; and it thus happens that alum miners and other miners may be met with in the same galleries or passages. We descend a square shaft, the mouth of which is visible in the middle of a field; and after a few lengths of narrow ladder have been descended, the mouth of a dark horizontal passage is reached—rendered by degrees dimly visible by the candles carried by the miners. At one place we encounter a party of coal-miners, with bits of lighted candle stuck in their caps, and occupied in the various operations incident to coal-mining. At another a party of lime-workers come into view, quarrying the hard white stone which forms the object of their labours, and baring the upper parts of their bodies to render the heat more endurable. At a third spot we fall in with the alum-miners, who do not meddle with the iron, the coal, or the lime, which are around them. The philosophy of this multiform mining is thus explained. There is a stratum of lime over a stratum of coal; and between the two is a stratum (varying from two to twelve inches in thickness) of ore containing most of the chemical elements of alum. When the coal has been for some years excavated, the alum ore, by being exposed to atmospheric influence, undergoes a slight mechanical and chemical change, which fits it for being used in the manufacture of alum. Sometimes specimens of ore are met with in which a hard slaty substance is interstratified with layers of a greenish white crystalline body; sometimes the ore presents itself as a brownish-black kind of coaly slate; but for the most part the ore clings to the roof of the excavated passages as a crumbling powdery substance. To collect, then, these various forms and stages of alum ore, is the work of the miners; and the pick and the shovel, the basket and the wheelbarrow, are dimly seen by the flickering light of the candles, acting their part in the operations.

Arrived again in open daylight we find a large area of ground occupied by steeping-pits and other arrangements for the manufacture of alum. If the ore is in the efflorescent state, it is steeped in water containing sulphate of iron and alumina, and the water is boiled, evaporated, and crystallized into alum; but if the ore is in the hard stony state, it requires to be roasted or burned in a large heap built up in the open air, before the elements which compose it can be acted on by the liquid solution.

Alum is colourless, inodorous, has an astringent taste, and crystallizes generally in regular octahedrons; but by the addition of alumina, and particular management, it may be made to crystallize in cubes. It is brittle, and easily reduced to powder; its specific gravity is about 1.731; water, at 60° Fahrenheit, dissolves about one-eighteenth of its weight of alum, and boiling water about three-fourths of its weight. The solution reddens vegetable blue colours strongly; when exposed to dry air, alum effloresces slightly on the surface, but it remains long without undergoing any change internally. When moderately heated, alum dissolves in its water of crystallization; if more strongly heated, the water is evaporated, and when exposed to a very high temperature, sulphuric acid is expelled, and there remains a mixture of alumina and sulphate of potash.

The above-named properties relate to *common* or *potash alum*. *Soda alum* is produced by the action of sulphate of soda on sulphate of alumina. Their properties are very closely allied to those of potash alum.

Alum is decomposed, not only by heat, but by many of the acids, alkalies, and earths. It is employed for a vast number of purposes. It is used in lake colours, dyeing, calico printing, leather dressing; and by candle-makers to harden the tallow and render it white. It is an ingredient in making pyrophorus; and in medicine it is employed as an astringent.

Mr. Cliff obtained a patent in 1845 relating to the alum manufacture, in which a double useful result is sought to be obtained. Many kinds of fire-clay used for making retorts, crucibles, and similar articles, contain an excess of alumina, which injures the quality of the articles made from them when at a high heat. Mr. Cliff proposes to take a very aluminous clay, such as is found at Wortley near Leeds; to grind it, calcine it, mix it with sulphuric or some other acid, dissolve the alumina out of it, evaporate the solution, and obtain alum from the residue by the usual chemical means. The earthy sediment, which results when all or nearly all the alumina has been removed, is then to be mixed up with ground native clay, to make a fire-clay fitted for retorts, &c. Many other patents have been recently taken out, for various improvements in the alum manufacture.

The proprietors of some of the chemical works near Newcastle intend to exhibit, at the great display of 1851, specimens of alum, in large masses, procured by the direct chemical union of the component ingredients.

ALU'MINA, the earthy oxide of aluminum, sometimes called argil, or argillaceous earth, constitutes the larger portion of all clays, and their plastic property is owing to it. In a pure state it is procured from alum, from which it derives its name. Alumina is widely diffused throughout the earth; the adamantine spar or corundum, the ruby, and sapphire, are alumina nearly pure and crystallized; these substances have not, however, any of the more obvious properties of common clay, for instead of being amorphous, soft, and diffusible through water, they are crystallized, are among the hardest substances in nature, and will not mix with water. The diaspore is a crystallized mineral, which consists almost entirely of alumina and water; and in North America another hydrate of alumina has been found, and called gibbsite.

Alumina is white, powdery, and light; it has neither taste nor smell, and it adheres to the tongue. It is insoluble in water. It shrinks considerably by heat, and may be fused at a high temperature. Alumina is not in itself either acid or alkaline; but it combines with numerous acids to form salts, among which the *acetate of alumina* is much employed in calico printing. It also combines with potash, soda, lime, and magnesia, so as to form salts called *aluminates*.

ALUMINUM, the metallic base of alumina, is prepared with too great difficulty to be useful in the arts in its separate state.

AMADO'U, *touch-match*, or *German tinder*, is a brown leathery substance prepared from the *Bolétus igniarius*, a fungus which grows on the trunks of cherry, ash, and other trees. The fungus is perennial, and increases yearly in size. The soft spongy substance of the fungus, after removing the outer covering, is cut into thin slices, and beaten with a mallet to soften it. In this state it is used for stopping hæmorrhages, and for other surgical purposes; and by subsequent boiling in a strong solution of saltpetre it is prepared for use as tinder, constituting the *German tinder* of the tobacconists. To render it very inflammable it is sometimes imbued with gunpowder, which gives it a darker colour.

On the Continent, before the use of congreve lights, tobacco-smokers were accustomed to carry about with them a box containing a little amadou and a small flint and steel.

AMALGAM, a compound of two or more metals, of which one is always mercury; and this circumstance distinguishes an *amalgam* from a mere *alloy*. Nature presents us with only one amalgam, which is of silver, and is termed by mineralogists *native amalgam*: it is met with either semifluid, massive, or crystallized. Klaproth found it to exist of 64 parts of mercury and 36 of silver, out of 100 parts. Most metals may be amalgamated with mercury, and the combination appears to depend on chemical affinity. When the cohesion of a metal is slight, as in the cases of potassium and sodium, or when its affinity for mercury is considerable, as in the instances of gold and silver, amalgamation takes place readily by mere contact. When, on the other hand, the cohesion of a metal is strong, or its affinity for mercury is weak, heat, or intermediate action, or both, are requisite to effect amalgamation. The density of an amalgam exceeds that of the mean of the metals; this and the tendency exhibited by one or both metals to oxidize, are indications of chemical combination. Antimony offers an example of metals which will not amalgamate without heat; in order to effect combination, it must be melted, and while liquid mixed with hot mercury. It has been stated, that they may be amalgamated by mixing the filings of the metal with powdered alum, and rubbing them together in a mortar with a little water; after trituration the alum may be washed out. By the intervention of tin or zinc, iron may be combined with mercury, and a double amalgam is formed. Platina also unites with mercury by the intervention of the amalgam of potassium, but not by direct action.

Amalgams are either liquid, soft, or hard; their form being dependent, in some cases, upon the quantity of mercury employed, and, in others, upon the nature of the metal amalgamated: thus, an amalgam consisting of eighty parts of mercury and one part of sodium, is solid, whilst a compound of fifteen parts of mercury and one part of tin is liquid. The liquid amalgams resemble mercury in appearance, except that the greater part of them flow less readily: solid amalgams are brittle. In general, amalgams are white; they are all crystallizable, and they form compounds of definite proportions. The amalgams of the more oxidable metals, as of potassium and sodium, are decomposed by exposure to the air and absorbing oxygen, and they decompose water with the evolution of hydrogen gas; the double amalgam of iron and zinc does not rapidly undergo any change, and is not attracted by the magnet. All amalgams are decomposed by a red heat, the mercury being volatilized, and the more fixed metals remaining. The process of amalgamation and decomposition is employed to separate gold and silver from their ores; the mercury obtained by decomposing the amalgams is distilled, and repeatedly used for the same purpose, with comparatively little loss. The amalgams of gold and silver are employed in the processes of gilding and plating. (For the mode of silvering the interiors of hollow glass globes, see MIRROR.) The amalgam of tin is largely used in what is termed silvering mirrors, and various amalgams of tin and zinc are employed for exciting electricity in the machine. Some curious effects result from the action of amalgams upon each other: if mercury be added to the liquid amalgam of potassium and sodium, an instant solidification ensues, and heat enough to inflame the latter metals is evolved. When, on the other hand, a solid amalgam of bismuth is put in contact wtth one of lead, they become fluid, and the thermometer sinks during their action.

Some of the French dentists use an amalgam of copper to fill the cavities of hollow teeth. It is gray, very hard, and adheres firmly in its place. There are many useful applications for it as a stopper to machines and chemical apparatus wherever other materials cannot conveniently be used. It is said to consist of 70 parts of mercury to 30 of copper.

AMALGAMATION is a term often used to indicate the process of separating gold and silver from their ores. It will suffice to refer to CALIFORNIA; GOLD; MERCURY; SILVER.

A'MAZON, or MARAÑON, or ORELLA'NA. This magnificent South American river (the largest on the globe) produces on its banks cacao, sarsaparilla, copaiba, caoutchouc, fine forest trees, and many other plants; and the river itself yields abundance of fish. But the slow progress of European enterprize in that region has yet done little to make its resources available, although steam navigation has begun to develope itself on the Amazon.

AMBER, a carbonaceous mineral which occurs in beds of lignite, in Greenland, Prussia, France, Switzerland, and some other countries. The greater portion of it comes from the southern coasts of the Baltic Sea, where it is thrown up between Königsberg and Memel. It is also obtained by mining at a distance of 200 feet from the sea, and at a depth of about 100 feet, and is found in small cavities. It is occasionally met with in the gravel beds near London, in which case it is merely an alluvial product. Amber occurs generally in small pieces, which are sometimes colourless, frequently light yellow, or deep-brown, and very commonly translucent.

The amber-gathering on the shores of the Baltic in 1844 was more abundant than was ever before known at the same spot. In the village of Kahlberg alone, where the amber-gathering is farmed, 20,000 thalers' worth of amber was picked up in the course of a few weeks. It is supposed, according to a paragraph in the *Elbing Zeitung*, copied into the English journals, that this increased quantity may have resulted from the violent storms which prevailed on the shores of the Baltic in the preceding winter, by which the treasure was driven up from the bottom of the sea.

Amber is rather harder than common resins, which it resembles in several properties: it is susceptible of a good polish, and when rubbed becomes electrical; indeed, the word *electricity* is derived from ἤλεκτρον, the Greek name for amber. Its density varies from 1.065 to 1.070: when bruised it exhales a slight aromatic odour; and when heated to 448° of Fahrenheit it melts, then inflames and burns with a bright flame, and emits a smell which is not disagreeable.

The subject of the origin of amber is one which has been much discussed. According to Berzelius it was originally a resin dissolved in a volatile oil or natural balsam; the proofs of this opinion are, he conceives, numerous; it has often the impression of the branches and bark upon which it has flowed and solidified; it often contains insects, some of which are so delicately formed that they could not have occurred except in a very fluid mass. Sir David Brewster concludes, from an examination of the optical properties of amber, that it is an indurated vegetable juice. Humboldt says, in his *Cosmos*, "The petrified wood which frequently surrounds amber had early attracted the attention of the ancients. This resin, which was at that time regarded as so precious a product, was ascribed either to the black poplar, or to a tree of the cedar or pine genus. The recent admirable investigations of Professor Göppert, at Breslau, have shewn that the latter conjecture is the more correct." Amber consists of a mixture of several substances, which are, a volatile oil, two resins soluble in alcohol and in ether, succinic acid, and a bituminous body that resists the action of all solvents, and which is the principal part of amber. Water does not act upon this substance; it does not even dissolve any of the succinic acid. Alcohol takes up a soft, yellow, limpid resin. Sulphuric and nitric acid both dissolve it.

Amber is employed for ornamental purposes in the manufacture of necklaces, &c. It is used also for preparing amber varnish, for obtaining a peculiar oil used in medicine, and it yields succinic acid employed in chemical investigations.

Mr. Stelling has recently introduced an improved method of making varnish from amber. The difficulty hitherto has been in melting the varnish: the subsequent incorporation with oil and the other ingredients is comparatively easy. The melting is effected in a copper vessel of peculiar construction, whereby the amber becomes liquid without any residuum, and without evaporation of its constituent elements; there is less danger from fire than in the older methods, and the vessel is not liable to burst, which the earthen vessels formerly used were apt to be.

The largest piece of amber at present known is in the Royal Cabinet at Berlin; it weighs 18 lbs. The sum of 5000 dollars is said to have been lately offered by some Armenian merchants, for a piece of amber weighing 13 lbs. This substance is joined and mended by moistening the surfaces with linseed oil, and strongly pressing them together, gently heating them at the same time. In the working of amber the material is wrought in a lathe, polished with whiting and oil, and rubbed with flannel. It becomes so electrical during the working that the workmen are said to suffer considerable inconvenience. By a careful application of heat the workmen are enabled to harden amber. The beautiful black varnish used by coach-makers is a very carefully prepared compound of amber, asphaltum, linseed oil, and oil of turpentine. Factitious or imitation amber is often prepared from shell-lac or gum copal.

Amber is admitted duty free, but manufactured articles in amber pay an import duty of 15 per cent.

AMBERGRIS, a substance of animal origin, found principally in warm climates, floating on the sea, or thrown on the coasts. The best comes from Madagascar, Surinam, and Java. It has been found in the intestinal canal of the *physeter macrocephalus*, mixed with the remains of several marine animals which have served it for food; on this account it has been supposed to be a morbid product, analogous to biliary calculi.

Ambergris of good quality is solid, opaque, of a bright gray colour, which is darkest externally, and intermixed with yellow or reddish striæ. When it is heated or rubbed it exhales an odour which is agreeable to most persons. It is sufficiently soft to be flattened between the fingers. Its specific gravity varies from 0.908 to 0.920. When ambergris is heated with boiling alcohol of specific gravity 0.833, until it is saturated, a peculiar substance, called *ambrein*, is obtained as the solution cools, grouped in mammillated, small, colourless crystals. Ambrein, thus obtained, is brilliant, white, and insipid; it has an agreeable odour. When heated upon platina foil it fuses, smokes, and is volatilized, leaving scarcely any residue; by dry distillation it becomes brown. It is very soluble in strong alcohol, either hot or cold, in ether, and in oils both fixed and volatile. Nitric acid converts it into a pecular acid, called *ambreic acid.*

Ambergris is used as a perfume; and as the alcoholic solution is the most odorous preparation of it, it is generally employed in that form.

Ambergris is admitted duty free.

AMBOYNA, one of the Molucca or Spice Islands, in the eastern seas, is a mountainous place, abundantly furnished with trees and underwood. Sulphur is produced among the hills, some of which are encrusted with a copious efflorescence of that mineral. The earliest visit made to Amboyna by any Europeans was in 1511, when the Portuguese traded to, and afterwards took possession of it.

They held it till driven out by the Dutch in the sixteenth century; about which time the English East India Company also wished to have a share in the valuable spice trade of this and the other Molucca Islands. From that time to the present, except for a short period during the last war, the island has belonged to the Dutch. The main object of the different European powers, who endeavoured to possess themselves of Amboyna, was to monopolize the trade in cloves, the cultivation of which spice forms the principal object of industry with the natives. With the desire of keeping the cultivation of the clove-tree completely within their power, the Dutch caused it to be extirpated from every island belonging to them except Amboyna, where they provided for a sufficient production of the spice, by obliging every native family to rear a certain number of clove-trees. In the prosecution of their plans the island was divided into 4,000 allotments, each one of which was expected to support 125 trees, and a law was passed in 1720 rendering it compulsory upon the natives to make up the full complement. The number of trees upon the island accordingly amounted to 500,000, the average produce of which exceeded one million of pounds of cloves annually.

AMBULATORY, in architecture, the space enclosed by a colonnade or an arcade. In the peripteral temple of the Greeks, the lateral or flanking porticoes are properly termed ambulatories; the cloister of a monastery is surrounded by an ambulatory or ambulatories. The aisles of the ancient Basilica, and those of the cathedral, or other large church, are sometimes called ambulatories.

AMERICA. This great continent has been made known to Europeans partly by the eagerness which commercial nations shew to extend the sphere of their operations, partly by mere national glory, partly by a love for geographical science, and partly by missionary zeal. So far as the commercial incentive has been concerned, we may take a rapid glance at the progress of its discovery.

The whole career of Columbus was in effect a carrying out of the commercial spirit which in his days marked the courts of Spain and Portugal. The riches of India having become known, a wish was entertained to find a western route thither; and in searching for this western route, Columbus discovered America. In his first expedition, made in 1492, he discovered San Salvador, Cuba, Hayti, and other islands of the West Indies, which he so named in ignorance that the vast Pacific intervened between them and India proper. In the next expedition Columbus discovered Jamaica. In a third, his discoveries included Trinidad, and the coast of South America near the Orinoco. The success of Columbus soon gave encouragement to private adventurers to the new world, one of the first of whom was Alonzo de Ojeda, who, in 1499, followed the course of Columbus to the coast of Paria, and, standing to the west, ranged along a considerable extent of coast beyond that on which Columbus had touched, and thus ascertained that this country was part of the continent.

In 1497, while Columbus was engaged in his researches, the coast of North America had been reached by an English vessel, commanded by Giovanni Gaboto, or Cabot, a Venetian settled in Bristol, who undertook an expedition in company with his son Sebastian, and explored a long line of the North American coast. In 1498, Sebastian Cabot, in another expedition, visited Newfoundland. In 1500, Gaspar Cortereal, a Portuguese, touched at Labrador; and Brazil was accidentally discovered by a Portuguese fleet under Cabral. The coast of the province of Tierra Firma, from Cape de Vela to the Gulf of Darien, was first visited by Bastidas, a Spaniard, in 1501. Yucatan was discovered by Diaz de Solis and Pinzon in 1508, and Florida by Ponce de Leon, in 1512. In the same year, Sebastian Cabot reached the bay since called Hudson's Bay. The Pacific, or Southern Ocean, was first seen from the mountain tops near Panama, by Balboa, in 1513, and, two years after, a landing was effected on the south-east coast of South America, about the mouth of the Rio de la Plata, by De Solis.

The French now began to participate in the zeal for adventure, and in 1524 an expedition was dispatched by Francis I., under Giovanni Verazzano, a Florentine, who surveyed a line of coast of seven hundred leagues, comprising the United States, and part of British America. But in 1508, Aubert, a Frenchman, had already discovered the St. Lawrence River. Jacques Cartier, also a Frenchman, in 1534 nearly circumnavigated Newfoundland, and entered the Gulf of St. Lawrence. The coast of California, on the west side of the northern division of the continent, was discovered by Ximenes, a pilot, who had murdered Mendoza, a captain, dispatched by Cortez on a voyage of discovery; the Gulf of California, or Sea of Cortez, was first entered by Francisco de Ulloa, another captain sent out by Cortez in 1539. The Spaniards subsequently undertook several unsuccessful voyages, but they did not abandon their hopes, and at the close of the 16th century Sebastian Viscaino advanced along the coast of New Albion as far as the Oregon or Columbia River.

Colonization in North America by England commenced in the time of Queen Elizabeth. Sir Humphry Gilbert was the first to attempt it, though he merely took formal possession of Newfoundland, in 1583; his half-brother, the celebrated Sir Walter Raleigh, in 1584, dispatched an expedition which discovered the country then called Virginia, and he made several attempts to colonize it without effect. The colonies of Virginia and New England were respectively planted in 1607 and 1620, under James I., and it is not a little remarkable that one hundred and six years elapsed after North America was first visited by Cabot, before a single Englishman had effectually settled in the country.

Within the last half century many exploring parties have traversed the interior regions of America. The recent discoveries of treasure in California have led to a new series of overland researches, some of them in connection with a proposed railway.

British researches in North America have been chiefly directed to the examination of the western coast, under Cook, Clarke, Meares, Vancouver, &c; and to arctic or north-west expeditions. In 1818 the British government commenced that series of expeditions which, aided by the Hudson's Bay Company, and by private enterprize, and conducted by Parry, John and James Ross, Lyon, Franklin, Richardson, Beechey, Scoresby, Dease, Simpson, Ray, King, Back, and others, have resulted in those discoveries which have become such a source of public interest in this country. Would that we could close the mention of them with any announcement of the safety of Sir John Franklin and his enterprizing companions!

The exploratory researches in South America have not been so numerous as in the north; but some of them have been of great value, both geographically and commercially: especially those of De la Condamine, Godin, Humboldt, Bonpland, Spix, and Martius.

When America was first discovered, a large part of it consisted of one vast forest, extending nearly from the Atlantic to the Mississippi, and from the Canadian lakes to the Gulf of Mexico—2,000 miles in length, with an average breadth of 1,000. Most of this vast forest yet remains; but the tract west of the Mississippi contains extensive plains. These plains are devoid of trees; but the lower parts of the Mississippi valley, with a portion towards the north, are still covered with a dense forest, spread interminably like an ocean. The *prairies* of this valley are found both on the east and west side of the channel of the river; they are extensive, elevated, and generally irregular tracts, without trees, though sometimes capable of producing them, covered in the spring with countless flowers and long grass, and often possessing a deep rich soil.

South America is rich in mineral produce. Gold is found in New Granada, Peru, Chili, La Plata, and Brazil; and diamonds have been for some time a part of the Brazilian exports. The silver mines in Peru are very rich, and in Chili there are mines of silver, lead, and sulphur; those of copper are still more abundant. There are mines of iron, sulphur, antimony, tin, lead, copper, and quicksilver, in Brazil; but the pursuit of the precious metals appears to have diverted attention from other mining speculations. America also sends to Europe pearls and other precious stones.

In North America we find the bison, the musk ox, the reindeer, the wapiti, the Virginian deer, the elk, the long-tailed deer, and the black-tailed deer of the Rocky Mountains; the Californian sheep, and the Rocky Mountain Goat. The most remarkable forms of American deer are the llamas, alpacas, and vicuñas, which tenant the craggy Andes. Long previously to the arrival of Columbus, the llama was domesticated and used as a beast of burden by the natives; its wool was manufactured into cloth, and its flesh supplied a wholesome food. Among the Rodents many are valuable as fur-bearing animals; of these we may notice the beaver, the musquash, the coypu, various species of squirrel, and the chinchilia of Peru and Chili. Many thousand skins of the beaver, of the musquash, and of squirrels, are annually imported into England from the northern regions of America; and an extensive trade in the skins of the coypu, improperly called *nutria* or otter, and also in those of the chinchilla, is carried on at Buenos Ayres. Bears are hunted by the fur traders for the sake of their skins, as are also various foxes, ermines, martins, polecats, wolverines or gluttons, lynxes and others. America now contains horses, horned cattle, sheep and goats; but these have been introduced since the time of Columbus. Horses and cattle exist in many parts of South America in great numbers, and wild herds roam the plains. They abound also in Mexico, and the great prairies of the western portions of North America.

In the United States the forests consist of pines and larches unknown in Europe, many kinds of oaks, locust-trees, black walnuts of enormous size, hickories and ashes. Tobacco, maize, and wheat, are the staple objects of cultivation.

At about the latitude of Virginia the region of cotton and rice begins. In the countries in and around the gulf of Mexico, besides indigo, coffee, sugar-cane and maize, (which here finds its native home,) the cocoa-tree, from whose seeds chocolate is prepared, is a most important species; the exportation of the seeds of this plant, which is found wild in the most burning districts, is valued at near 80,000*l.* sterling annually. Pineapples grow wild in the woods; the American aloe yields, when wounded, an abundance of sweet fluid, which is fermented into an intoxicating drink called *pulque*, and distilled into an ardent spirit known by the name of Vino Mercal. In the low woods of Honduras are found enormous forests of mahogany and logwood trees. It is here also that the tamarind and the lignum vitæ are found, the vanilla, and the jalap convolvulus. As we proceed farther and farther southward, the vegetable growth gradually changes, and all the rich and varied produce of South America meets the view.

Under the names of the chief countries, rivers, and towns of America, will be found sundry details illustrative of the produce, manufactures, and commerce of this great continent.

AMETHYST. The *Occidental* or *Common Amethyst* is a variety of quartz or rock crystal, which is met with in many parts of the world, as India, Siberia, Sweden, Germany, Spain, &c. It occurs in various forms, massive, in rounded pieces, and crystallized. The primary form of the crystal is a slightly obtuse rhomboid; but it is usually found in the secondary form of a six-sided prism, terminated at one or both ends by a six-sided pyramid. The crystals of the amethyst vary from diaphanous to translucent, and they exhibit various degrees of splendour, both externally and internally. The fracture is commonly conchoidal, and the fragments are of indeterminate form. The colour is violet or purple violet. The amethyst is sufficiently hard to give fire with steel, and to scratch glass.

The composition, by means of which the best imitation of the amethyst can be produced in glass, is said to be the following:—1000 parts of trass or colourless transparent glass; 8 parts of oxide of manganese, 5 parts of oxide of cobalt, and 0·2 parts of purple of cassius.

AMIANTHUS. [Asbestus.]

AMIENS, in the department of Somme, in France, has considerable trade and manufactures. Velvet, plush, camlet, quilting, serge, drugget, fine kerseymere, hosiery, and other goods, linen, cotton, and woollen, are either entirely manufactured, or, being brought to Amiens from other places in an unfinished state, are prepared for sale in other parts of the country or for exportation. There are also paper-mills and bleaching-grounds. The town serves as a mart for the numerous manufactures of the neighbourhood as far as the confines of the department. The total value of the commercial industry of the district, of which Amiens is the centre, was estimated in 1843 at 40,000,000 francs. The value of raw silk, wool, and cotton used in manufactures is set down at between 5 and 6 millions of francs, while the value of the products is stated to be between 15 and 16 millions of francs. The railroad between Amiens and Abbeville was opened in 1847.

AMLWCH, a town in the island of Anglesey in Wales, was an insignificant village till 1768, about which time the celebrated and highly productive *Parys* copper mines, in the neighbouring mountains, were discovered by the united exertions of Sir Nicholas Bayley and Messrs. Roe. Soon afterwards the *Mona* mine was discovered, in the same mountains; and both have since proved highly profitable to the Marquis of Anglesea and other proprietors, and also to the town of Amlwch. At one time, in the history of these mines, the copper ore was found in large conglomerate masses, which admitted of being quarried in open day; at another, it occurred in regular veins or lodes; and as the excavations advanced, the metal was found more and more mixed with earthy matters, so that, at the present time, the ore (chiefly sulphuret of copper) does not contain more than 4 per cent of metal, and the produce is far less remunerative than formerly. At one time the mines gave employment to 1500 men; the stock of ore on hand often exceeded 40,000 tons, and the works for smelting the ore were of great magnitude. At the present time (1850) about 1000 persons are employed at the mines, of whom 100 are engaged at the smelting works. The 2nd of March, the day on which the vein of ore at Parys mine was discovered, is kept as an anniversary holiday at Amlwch. A capacious harbour has been excavated out of the solid slate rock, for the reception of the vessels connected with the copper trade.

AMMO'NIA, the modern name of the *volatile alkali*, formerly so called to distinguish it from the more fixed alkalies; it is a gaseous body, and was first procured in that state by Priestley, who termed it Alkaline air. He obtained it from sal ammoniac, and hence the present name of the alkali.

Ammonia, like all the other alkalies, is a compound substance; it consists of nitrogen and hydrogen, in the proportion of one atom of the former to three of the latter; but these two cannot be made to combine by direct action. Ammonia is colourless, transparent, and of course invisible; possessing the elasticity and mechanical properties of atmospheric air. The smell is peculiar and extremely pungent, and its taste is highly acrid. An animal put into it is immediately killed, and a taper when immersed in it is extinguished. The density of ammoniacal gas is to that of atmospheric air, nearly as 0·5902 to 1; 100 cubic inches weigh rather more than 18 grains. It acts strongly as an alkali, turning vegetable blues green, and yellows reddish brown, and saturates acids, forming various salts. The aqueous solution is colourless, transparent, and has the pungency and alkaline property of the gas: by exposure to the air the ammonia escapes, and by the application of heat it is expelled from the water.

Ammonia is produced in many different ways, both natural and artificial. Almost every animal substance contains the elements of ammonia; and when such a substance is exposed to decomposition, oxygen and carbon combine to form carbonic acid, while hydrogen and nitrogen form ammonia; and the two together form carbonate of ammonia. If such substances as bones, hoofs, or horns, are heated in iron cylinders, ammonia is separated in combination with many other matters, and, after purifying, a liquid called *spirit of hartshorn* results. Vegetable matter containing gluten, coal-soot, and coal itself, may also be made to yield ammonia. Ammonia is produced in small quantities by many different chemical processes, but those mentioned above are the chief sources. By the heat of a spirit lamp, ammonia forms with sodium or potassium a yellowish crust of those metals, though the surfaces remain brilliant and smooth. When passed over melted iron or copper, ammonia is absorbed; and by voltaic action ammonia may be made to combine with mercury, producing an amalgam which is soft at 70° or 80° Fahrenheit, but a firm crystalline body at 32°. Ammonia combines with many of the metals to form *ammoniurets*. In many of its practical applications ammonia is used in solution in water, called *liquid ammonia*, as being more convenient than in the gaseous form.

Ammonia produces many valuable salts, when combined with acids; and those salts, as well as liquid ammonia itself, play an important part in many chemical manufactures, but still more in medicine. The carbonate of ammonia is much used by the bakers of fancy bread and light pastry. With a few drops of any aromatic essential oil it forms smelling salts. Crude sulphate of ammonia forms excellent manure. Nitrate of ammonia forms a freezing mixture with water. Muriate of ammonia is employed in dyeing; it is also used to impart pungency to snuff.

AMMONIAC, GUM, a concrete juice procured in Persia and other parts of the East, from the *dorema ammoniacum*. The juice exudes from the stalk, and is also obtained from the root. It consists of grains of various sizes, usually called *tears;* their colour is whitish, but they become yellow by the action of the air; they are shining, opaque, irregular in shape, and more or less globular; when cold, ammoniac is rather hard and brittle; it softens by the heat of the hand, but does not entirely liquify at a stronger heat. The smell is peculiar and disagreeable, and the taste is nauseous, at first mucilaginous and bitter, and afterwards acrid. Its specific gravity is 1·207. When distilled with water it loses its volatile oil, and becomes inodorous; the distilled water has the odour of the gum, and small drops of limpid colourless oil float on its surface. According to Bucholz, ammoniac consists (in 100 parts) of 72 parts of resin, 22·4 parts of gum, and slight traces of bassorine, water, &c. It is used both in medicine and in some manufacturing processes.

AMO'MUM. [CARDAMOMS.]

AMOY, a city and port of China, in an island of the same name, near the coast, is the emporium of the commerce of the province of Fokien. The merchants of Amoy are among the most wealthy and enterprising in the Chinese empire; they have formed connections all along the coast, and have established commercial houses in many parts of the eastern Archipelago. During the south-west monsoon, they freight great numbers of their smaller junks at Formosa with sugar and rice, which they sell at various ports to the northward, returning home with cargoes of drugs. Above 300 junks of the largest class—some of them 800 tons burden—belong to Amoy, and trade with Borneo, Manilla, Macassar, Java, the Soo-loo Islands, Singapore; and with Bankok, the capital of Siam.

Europeans were allowed to trade to Amoy from 1675 to 1681; but after the latter date, such trade was almost entirely prohibited, until the recent arrangements with the English government. On the 26th of August, 1841, Amoy was captured by the British; by the treaty of Nanking, dated August 29, 1842, this port, among others, was opened to our trade, and British subjects and a British consul allowed to reside at Amoy. By a supplementary treaty, dated October 8, 1843, a tariff of imports and exports was established, and other foreigners admitted to the same privileges as British subjects.

AMPHIDESMA, is the name of a genus of bivalve shells, the cartilages of some of the larger species of which, as the mother-of-pearl shells, are sold by the jewellers under the name of *peacock-stone* or *black opals*. They are not so much used now as formerly, but they are still much sought after on the continent, especially in Portugal.

AMPHIPROSTYLE, is used to designate structures having the form of an ancient Greek or Roman parallelogramic temple, with a prostyle or portico on each of its ends or fronts, but with no columns on its sides or flanks.

AMPHITHE'ATRE, was a building used by the Romans for the exhibition of gladiatorial combatants, and of fights with wild beasts. The word literally means a double theatre, or one composed of two theatres. In the theatre the spectators sat in a semicircle placed opposite to the straight line of the stage; in the amphitheatre, which was of an elliptic form, the seats were placed all round.

The form of an amphitheatre, then, is generally an ellipse, with a series of arcaded concentric walls, separating corridors which have constructions with staircases and radiating passages between them. It enclosed an open space called the aréna. The innermost concentric wall bounded the arena, and was from 10 to 15 feet above its level: from this wall an inclined plane ran upwards and outwards over the intermediate wall, staircases, and corridors, to a gallery or galleries over the outermost corridors. The inner and upper part of the inclined plane was covered with a graduated series of benches following the general form of the plan; these benches were intercepted at intervals by radial passages leading by a more easy graduation to and from the staircases which passed through the substructions of the benches to the corridors. These corridors, in the principal stories, continued uninterruptedly all round the edifice, and afforded easy access to every part. In cases where the radiating passages through the bank of benches were few, concentric platforms went round to make the communications complete. The external elevation of an amphitheatre was determined by its internal arrangement and construction, and it generally had two or more stories of open arches, which were necessary to give light and air to the corridors and staircases.

Roman amphitheatres were first constructed of timber. Afterwards they were constructed of brick or stone.

The amphitheatre of the Romans was raised, for the most part, within the town or city, on the level ground, of costly magnificence, and generally of enormous extent. Almost every important Roman colony or city bears indications of a constructed or excavated amphitheatre. The Colosseum at Rome would contain above 80,000 persons; and even the little city of Pompeii contains the remains of an amphitheatre. The Roman garrisons appear to have contented themselves with camp-built amphitheatres alone. Of this sort,—the castrensian amphitheatre,—we have indications still existing in England; the principal are at Cirencester and Dorchester; but these were originally little more than mere excavations or turf-built cinctures, made up with what walling was absolutely necessary to form the grand concentric bank of benches.

The largest amphitheatre ever built was the Flavian Amphitheatre at Rome, commonly called the Colosseum, which was begun by Vespasian and finished by his son Titus, A.D. 80. The plan and elevation can be made out almost completely from the existing remains. It covers more than five acres. The dimensions as given by different authorities, vary a little, but the largest external diameter is about 613 feet, and the shorter diameter about 510 feet. The external elevation is composed of three series or stories of attached or engaged columns with their usual accessories, and a pilastraded ordinance, forming a species of attic, which is pierced with windows,—one in every other interspace. The crowning entablature is made bold and effective by deep modillion blocks or consoles occupying the whole depth of the frieze. Next in size to the Colosseum, of existing structures of the kind, is the Amphitheatre of Verona. The outer dimensions of this structure were 500 feet by 404 feet. The amphitheatre of El Jemm (Tisdrus) in Tunis is 429 feet in extreme length.

History will record that in the year 1851 there was raised a building in London, nearly capable of containing three of the greatest amphitheatres,—a building not devoted to the bloody contests of the arena and the gratification of national pride and individual bravery, but for the promotion of goodwill, and the cultivation of the most valuable arts, amongst all the nations of the earth.

AMPHITYPE. At the York meeting of the British Association, in 1844, Sir John Herschel described a variety of the 'photographic' process to which he gave the name of *Amphitype*. The paper is saturated with one among several chemical solutions named by him; and the paper so prepared and dried takes a negative picture, in a time varying from half an hour to five or six hours. The impression produced varies in apparent force, from a faint and hardly perceptible picture, to one of the highest conceivable fulness and richness both of tint and of detail: the colour being a rich soft brown. The pictures in this state are not permanent: they fade in the dark, though with different degrees of rapidity; but the picture is only dormant; it may be restored, with a change of character from negative to positive, and of colour, from brown to black. This is effected by the employment of a solution of per-nitrate of mercury, into which the paper is steeped; a long and careful process of rinsing, drying, heating, and smoothing follows, by which a changed picture is produced, very much resembling the effect of a copper-plate engraving on a slightly yellow paper. It is from the production, by one and the same action of light, of either a positive or negative picture, according to the subsequent manipulation, that the name of *amphitype* has been applied to the process. The solutions in which the paper is originally steeped are any of the following,—ferro-citrate or ferro-nitrate of mercury: the metal being either the protoxide or the peroxide, or being superceded by the protoxide of lead; and the nitric acid being substituted for those above named. Steepings in these solutions are to alternate several times with steepings in solutions of the ammonia-tartrate or ammonia-citrate of iron.

Another curious process, which is an *Amphitype* on a different principle, also described by Sir John Herschel, depends on the steeping of a piece of paper, before the photographic process, in a solution of ferro-tartrate of silver. If the paper, immediately on being removed from the photographic camera, be placed for a few seconds with its *back* exposed to the sunshine, a positive picture, the exact complement of the negative one on the other side, slowly and gradually makes its appearance, and in half an hour or an hour acquires a considerable intensity, though unequal to the original picture on the other side in sharpness of detail. This is one of the most striking results in the whole range of photography. [DAGUERROTYPE; PHOTOGRAPHY, &c.]

A'MPHORA was an earthen vessel, used by the Greeks and Romans to hold liquids. It received its name from its two ears or handles. It is generally two feet or two feet and a half in height; and the body, which is usually about six inches in diameter ending upwards with a short neck, tapers towards the lower part almost to a point. The attic amphora contained three Roman urnæ, or 72 sextaries, equal to about nine gallons English imperial-measure. The Roman, sometimes called the Italic amphora, contained two urnæ or 48 sextaries, about six gallons. There are specimens of earthen amphoræ in the British Museum, which are supposed to have been used as funeral urns.

There was another amphora among the Romans, which was a dry-measure, and contained about three bushels.

AMRITSIR, or UMRITSIR, the holy capital of the Sikhs, is a large city in the state of Lahore. It has a considerable trade in the shawls and saffron of Cashmere, and is a place of great opulence, owing to the resort of merchants and to its being the residence of some bankers of extensive dealings. Its native manufactures are confined to coarse cloths and inferior silk goods. It is one of the most flourishing commercial towns in Northern India. It fell into the hands of the British in 1848.

AMSTERDAM, the chief city of Holland, is one of the most commercial places in Europe. The dock accommodation is fitted for a large number of merchant ships. The docks front the mouth of the river Y (an arm of the Zuider Zee), and are entered and secured by sluices. In the north-eastern quarter is the Nieuw Oostelijk Dok, the National Dockyard, and the island of Kattenburg, in which are the quays and warehouses of the East and West India Companies, the Arsenal, and the Admiralty buildings. West of the Dam Rack lies the Haring Packerye, or Herring Packery Tower, in the neighbourhood of which all the business connected with the export of herrings used to be transacted. Further west is the Nieuw Westelijk Dok.

The harbour is spacious and the water deep; it has recently been much improved by the construction of the Oostelijk and Westelijk Docks, which are capable of containing 1000 large vessels, and are closed by large sluice gates. Owing to a bank (the Pampus) at the point where the Y joins the Zuider Zee, large vessels going and coming by that sea are obliged to load and unload a part of their cargoes in the roads. The navigation of the Zuider Zee also is very difficult and intricate by reason of its numerous shallows. To improve the access to the port, the Helder Canal, capable of admitting the largest class of merchantmen, was cut from the north side of the port of Amsterdam to Newdiep, opposite to the Texel, a distance of 50 miles. By this canal the Pampus is avoided, as well as the difficult navigation of the Zuider Zee, where ships were frequently detained for three weeks; and vessels can get to and from Newdiep with out any risk in 18 hours Steam-boats ply from Amsterdam to Campen on the Yssel, from whence other steam-boats ply to the towns on the Yssel and the Rhine.

Amsterdam has some manufactures of wool, cotton, linen, and silk; its diamond-cutting and jewellery retain a good repute; but its sugar refineries, soaperies, distilleries, tanneries, oil works, tobacco manufactories, and ship building, are the most valuable branches of industry. The various handicrafts and ordinary fabrics common to all large towns are also carried on in Amsterdam. It has also some glass works and iron works. The imports principally consist of sugar, coffee, spices, tobacco, cotton, tea, dye-stuffs, wine and spirits, wool, grain, hemp, flax, pitch, metals, cotton and woollen stuffs, hardware, rocksalt, coal, &c. The exports are cheese, butter, seeds, rape and linseed oils, linen, spices, coffee and sugar from Java, tea, tobacco, indigo, cochineal, cotton, and other eastern and colonial products. About 260 large ships belong to Amsterdam, which are employed in the East and West India trade: 15 small vessels are engaged in the herring and whale fisheries. Upwards of 4000 vessels enter the port annually; and about the same number leave it. The imports in some years have exceeded £ 8,000,000 sterling.

By the adoption of the system of free navigation by the Dutch government, following the recent example of England, the commerce of Amsterdam will doubtless be greatly increased. The new Dutch Navigation Acts, which came into operation on the 15th September, 1850, and will apply to her colonial possessions at the beginning of 1851, will afford absolute freedom of navigation at the Dutch ports, at home and abroad.

AMULET, in barbarous Latin, *Amulētum*, or *Amoletum.* An amulet hung round the neck, or carried in any other way about the person, is absurdly believed to have the effect of warding off morbid infections and other dangers, and even of curing diseases by which the body has been already attacked. The belief in the efficacy of amulets has subsisted at some time among almost every people. The anodyne necklace, which consists of beads formed from the roots of white briony, and is sometimes hung around the necks of infants with the view of assisting their teething, is an instance of the still surviving confidence in the medical virtue of amulets. Such also is the belief entertained by seafaring people, that a child's caul on board their ship will preserve them from being lost. In exhibitions of art, ancient and mediæval, amulets are often to be met with of curious construction.

AMYGDALIN, a substance obtained from bitter almonds after the fixed oil has been expressed. Its properties are—that it has the form of small, white, pearly, crystalline plates, which are inodorous and nearly tasteless. It is very soluble in water, both hot and cold; a hot solution deposits brilliant prismatic crystals in cooling, which contain water.

AMYGDALUS, is the botanical name for several plants, of which the almond is the principal. [ALMOND.]

AMYRI'DEÆ, the botanical name for a natural order of plants consisting of tropical trees, the leaves, bark, and fruit of which abound in fragrant resin. The odoriferous substances called *gum elemi*, *bdellium*, and *resin of Coumia* are all produced by different species of amyrideæ.

ANACARDIA'CEÆ, or the Cashew tribe, is a natural order of plants, consisting exclusively of woody plants, abounding in an acrid resin. Their juice is often used as a kind of varnish, for which it is well adapted, in consequence of its turning hard and black when dry. It is, however, often dangerous to use, because of the extreme acridity of the fumes, which are apt to produce severe inflammation in many constitutions. One species, *Anacardium Occidentale*, if wounded in the stem, yields abundantly a milk, which, when inspissated, becomes intensely black and hard, besides which it secretes a gum not inferior to gum arabic. The nut is a kidney-shaped body, containing in abundance, beneath the outer shell, the black caustic oil of the order, which, when volatilized by heat, as happens in the process of roasting, is apt to produce erysipelas, and other disagreeable affections in the face of persons standing over the fumes; the kernel is a well known wholesome article of food. In the West Indies it is used as an ingredient in puddings, is eaten raw, and is roasted for the purpose of mixing with Madeira wine, to which it is thought to communicate a peculiarly agreeable flavour.

ANACARDIUM INK. [INK.]

ANA'LYSIS. Chemical analysis is the separation of compound bodies, either into their simpler or their elementary constituents. When merely the number and nature of these are ascertained, it is termed *qualitative* analysis; but when their proportions also are determined, the analysis is *quantitative*. If the analysis consist only in determining the quantities of the *simpler* constituents of a compound, it is *proximate*, as when carbonate of potash is separated into carbonic acid and potash: but when the operation is extended, and the carbonic acid is resolved into carbon and oxygen, and the potash into potassium and oxygen, the analysis is *ultimate*; for neither carbon, oxygen, nor potassium (in the present state of our knowledge) is divisible into two or more kinds of matter.

ANAMORPHO'SIS is such a representation of an object that, except when viewed from a particular point directly, or in a cylindrical mirror, or through a polyhedral lens, it will appear to be distorted, or disconnected, or to be a view of something very different from the original object. Such representations are only made for the amusement of young persons, and are of no artistic importance.

ANASTATIC PRINTING. Early in the month of November, 1841, the proprietors of the *Athenæum* received from a correspondent at Berlin, a reprint of four pages of the number of that journal which had been published in London only on September 25th. The copy was so perfect a facsimile, that had it not come to hand under peculiar circumstances, it would have been taken for two leaves out of a sheet actually printed in London; the observable difference was, that the impression was somewhat lighter, and the body of ink less than usual. In reply to further inquiries, the correspondent at Berlin could only discover that the secret was said to be in the hands of a person at Erfurt. He had seen a fac-simile of an Arabic MS. of the 13th century; and another fac-simile of a leaf of a book printed in 1483—both such close copies as hardly to be detected from the originals, and both taken without injury to the originals. It was also stated that a prospectus was issued at Berlin, of a pirated edition of the *Athenæum*, to be produced in a similar way, and sold at a low price.

In January 1845, the *Athenæum* was enabled to announce that the inventor or discoverer of the method was a M. Baldermus, who had communicated the discovery to a person in London; and to convince the proprietors of that journal of the reality of the method, a page of *L'Illustration*, French journal, was faithfully copied in a quarter of an hour. The method became known by the name of *Anastatic printing*; and many of the London journals directed attention to the subject. In the *Art Union* for February, 1845, pages 40 and 41 of the number are printed from zinc plates obtained by the Anastatic process. The compositors "set up" in the usual way, sufficient matter to fill up two quarto pages of the work, leaving spaces for three wood-cuts, three drawings, and a few lines of writing in pen and ink, which were properly adjusted to the blanks left for them. All were alike copied or transferred to the zinc plates, and then printed from to the number of several thousands. The impressions are fainter and less distinct than those from the original types, but they are unquestionably remarkable.

Professor Faraday explained the rationale of the Anastatic process in 1845, at the Royal Institution. The process depends on a few known properties of the articles employed. 1st. Water attracts water; oil attracts oil; but each mutually repels the other. 2nd. Metals are much more easily wetted with oil than with water; but they will readily be moistened by a weak solution of gum. 3rd. The power of wetting metals with water is greatly increased by the addition of phosphatic acid. 4th. A part of the ink of any newly printed book can be readily transferred by pressure to any smooth surface beneath; if, for example, a corner of a newspaper be fixed on a white sheet of paper, and then pressed or rubbed with a paper knife, the letters will be distinctly seen in reverse on the paper; and indeed every one knows that if a book be bound too soon after the printing, the pages become disfigured by the *setting off* or transfer of the ink upon the opposite pages. From these data the rules for the process are derived. The printed paper, whether letter-press or engraving, is first moistened with dilute acid, and then pressed with considerable force by a roller on a perfectly clean surface of zinc; by which means every part of the sheet of paper is brought into contact with the plate of zinc. The acid, with which the unprinted part of the paper is saturated, *etches* the metal, while the printed portion *sets off* on it, so that the zinc surface presents a reverse copy of the work. The zinc plate, thus prepared, is washed with a weak solution of gum in weak phosphatic acid; this liquid is attracted by the etched surface, which it freely wets, while it is repelled by the oil of the ink in which the writing or drawing on the plate is traced. A leathern roller, covered with ink, is then passed over the plate, when a converse effect ensues; the repulsion between the oil, ink, and watery surface over which the roller passes, prevents any soiling of the unfigured parts of the zinc plate; while the attraction between oil and oil causes the ink to be distributed over the printed portions. In this condition the anastatic plate is complete, and impressions are pulled from it by the common lithographic process. When it is required to apply the anastatic process to very old originals, which do not set off their ink on pressure, the page or print is first soaked in a solution of potash, and then in a solution of tartaric acid: by which is produced a perfect diffusion of minute crystals of bi-tartrate of potash through the texture of the unprinted part of the paper. As this salt resists oil, the ink roller may now be passed over the surface without transferring any of its contents, except to the printed parts. The tartrate is then washed out of the paper, and the operation is proceeded with as before, commencing with the moistening by nitric acid.

In No. 1135 of the *Mechanic's Magazine*, it is stated that Mr. Jobbins, the lithographic printer, took copies of printed pages by a process analogous to that of anastatic printing, as far back as the year 1840; and in the same number Mr. Cocks of Falmouth states "In the year 1836 I introduced a process for the transferring of copper plate engravings (by the old masters), as well as letter-press printing, &c., to stone, zinc, tin, pewter, type-metal, fusible metal, lead, copper, glass, &c., and had impressions taken from each; but the original subjects were destroyed by the chemical agents used. Since that time I have succeeded in transferring prints and letter press without even soiling the originals, fixing the same on metal, wood, or paper, and printing from the form any number of copies. The process is so faithful in its operation, that the finest line of the etching needle is preserved." It is evident, indeed, that anastatic printing is but an extension of processes known long before in England.

In 1848 Mr. Strickland and Mr. Delamotte instituted experiments with a view to ascertain how far the anastatic process would be available as a substitute for lithography. They succeeded in transferring or printing from drawings made on paper with lithographic chalk; within an hour after the drawing was made, a perfect anastatic *fac-simile* was produced, hardly to be distinguished from it. The chief difficulty here seems to be the production of a kind of paper which shall possess a surface similar to lithographic stone. A mode has been devised of imparting to India paper a clear sharp granular surface, well fitted for the purpose as far as regards surface; but it is almost too tender in substance. Mr. Strickland found that *metallic paper*, used for metallic pencils, had the required surface. For fine subjects copied in this way, it is essential that the lithographic chalk be of a hard quality; and cut to a fine point.

ANATOMICAL MECHANISM. Considerable ingenuity is exercised in providing mechanical aid for those who, by amputation or other causes, have been deprived of limbs. A few descriptive details on this subject will be found under ARTIFICIAL LIMBS.

ANATTO. [ARNOTTO.]

ANCHOR. Under some form or other anchors must have been as ancient as ships; and they are accordingly mentioned by Greek and Latin authors, by whom also the invention, like many others which from clumsy beginnings have passed through different stages of improvement, is ascribed to various persons. The first anchors were probably only large stones or crooked pieces of wood loaded with heavy weights, but among the Greeks, latterly, they were made of iron; of these the earliest had but one fluke, afterwards the other was added, and finally they were furnished with stocks. Each ship had several, of which the principal one was called ἱερα or sacred, and was reserved for the last extremity. This corresponds to that which has since been denominated the 'sheet anchor.'

The number of anchors carried by a ship have been finally reduced to four principal ones, all of which are disposed at the bows. These are the best and small bowers (bowyers), the sheet, and the spare anchor, and to them are added the stream and the kedge anchors, which are used for particular purposes, and are generally carried 'in-board.'

Every complete anchor has a *ring* by which it is suspended, a *stock* or cross-piece immediately below the ring, a *shank* or perpendicular bar, two *arms* proceeding in opposite directions from the lower end of the shank, a *palm* or *fluke* at the end of each arm, and a *bill* or *peak* at the end of each fluke.

When the anchor is let go in any manner from the vessel's side the heaviest end, or crown, will tend to become the lowest part, and the whole mass having reached the bottom will most commonly fall upon the crown and on one end of the stock; from this position therefore the anchor is to be canted or turned over before it can hold. Now, it is evident that if the stock were very short, the pull of the cable would tend rather to drag the end of the stock along the bottom than to lift up one of the flukes, as must be done in canting the anchor; whereas, if the stock were longer, the cable would act with increased leverage, whatever might be the length of the shank; hence the longer the stock, within the practical limits of stowage, the more certainly will the anchor turn properly; and, when hooked in the ground, the more powerfully will it resist any effort to overset it.

When the anchor has been turned, the stock then lying horizontally on the ground, and the point of a fluke touching the ground, it is evident that the force exerted by the ship to draw the anchor towards itself, compounded with the weight of the anchor (exclusive of the stock, and diminished by about one-seventh on account of the loss of weight in water), will produce a resultant force by which the fluke is made to enter the ground. An anchor, when 'dragged,' always tends to rise out of the ground, and does not again sink till it rests.

In *lifting* or *weighing* the anchor, the cable acting perpendicularly to the end of the shank, tends to break it, and hence the thickness of the shank should increase with its distance from the ring; also the breadth of the shank should be downwards, and the like holds good of the arms, the chief dimension of which should be in the plane of the cable and shank, thus opposing the greatest strength to the greatest strain.

Besides the strains to which an anchor is exposed by its office, it is liable to accidents; for instance, an anchor let go on a rocky bottom has been found, on heaving it up, to have lost an arm, which was probably caused by its striking against a rock obliquely in its descent; again, the shank has been found broken in the middle, though this does not seem to have been accounted for satisfactorily; and it may here be observed generally, that the anchor descends much more swiftly with a chain-cable than a hemp one, for the stiffness of the hemp opposes a retarding force, while the greater density of the chain adds a continually accelerating force.

The principal dimensions of the anchors in the navy may be stated shortly thus:—calling the shank 10, the arm is about 3, the breadth and depth of the palm about half this, the thickness or depth of the shank varies from ·4 to ·6, and the breadth about four-fifths of these, the edges being rounded. The weight of an anchor of 10 feet in length is about 11·4 cwt., and since, if the forms of all anchors were alike, the weights would be as the cubes of the lengths, the weight of any anchor might be found by multiplying the cube of its length by ·0114. Thus the weight of an anchor of 14 feet in length would be $14^3 \times \cdot 0114 = 313.$ cwt.; the weight of this anchor is, in practice, 30 cwt., hence as far as 30 or 35 cwt., the rule is near enough, but for larger anchors it gives the result too small, because their thickness is made greater in proportion. The weight of the anchor includes that of the ring. A general rule in the navy is to allow 1 cwt. to a gun; thus, an 80 gun ship would have an anchor weighing 80 cwt. A merchant-ship of 200 tons having an anchor weighing 10 cwt., 5 cwt. are added for every additional 100 tons; thus, a ship of 300 tons would have an anchor of 15 cwt., and so on. Small vessels require heavier anchors in proportion than large vessels; the sea, sudden gusts of wind, and the pull of the cable, affect the larger vessels less, and they thus preserve a steadier strain.

As to the cost of an anchor, the labour per cwt. is about 24*s.* for an anchor of 10 cwt. and under, and for the largest anchors about 3*l.*; the value of an anchor of 95 cwt., including the iron at about 9*s.* 9*d.* per cwt., is about 300*l.*

The stock consists of two beams of oak, bolted and hooped together; the length is that of the shank and half the diameter of the ring; it is square; the side at the middle is an inch to a foot of the shank, and tapers to half of this at the end. Such a stock is nearly one-fourth of the weight of the anchor. Lieutenant Rodgers has proposed a solid stock of African oak, for the greater convenience of stocking or unstocking. Of late years iron stocks, whose weight is from one-fourth to one-fifth of the anchor, have been much used.

Numerous improvements have been brought forward within the last few years in the form and manufacture of anchors. Lieutenant Rodgers has patented a hollow-shanked anchor, intended to combine strength with lightness. Mr. Pering has introduced a method of forming the arms of anchors by splitting or bisecting the bars which form the shank, and turning the ends back in contrary directions. Mr. Meggitt has patented an anchor in which the flukes are very little broader than the arms. It would be needless to enumerate all the improvements introduced or suggested; but among the changes proposed in the construction of anchors, the most remarkable is, perhaps, that which was brought forward by Mr. Porter, for the purpose of avoiding the consequences of 'fouling,' by the cable passing over the exposed fluke of the anchor when the vessel is swinging in a tide-way, and injury to the vessel herself in the event of settling upon her anchor. The peculiarity consists in giving to the arms a freedom of motion round a pivot or bolt at the end of the shank. The arms and flukes are forged independently of the shank, and have a hole drilled transversely through the centre for the reception of the iron bolt which connects them with the shank. The effect of this construction is, that when the anchor, after being dropped, rests upon the ground, it assumes a position in which the lower peak is in contact with the inferior surface of the shank, and the upper peak is as far as possible from it. The slightest movement of the cable then suffices to bring the anchor to a position in which the lower peak is favourably situated for penetrating into the ground: the penetration then takes place, and at length the shank and stock lie flat on the ground, the upper fluke being close upon the top of the shank.

Whether we view the forging of an anchor under the old state of things, or now that Nasmyth's hammer works such wonders, it is a striking exhibition of industrial art. The shaft of a first class anchor, nearly twenty feet long by ten or twelve inches thick, is too ponderous to be worked out of one piece of metal; and it has consequently to be built up of many pieces. Forty or fifty bars are sometimes laid together in a group, to be welded into one mass by powerful blows while at a white heat; but in modern times a smaller number of wider bars are more frequently used. The bundle of bars is brought to a highly heated state, in a kind of oven formed wholly of coals, which completely surround the iron; but as the length of the shank is so great, only so much of it is heated at once as can be forged before it cools down too low. The fire is urged by ten or a dozen men (the same who afterwards apply their lusty arms to the hammers); and when the mass is brought to a white heat, it is drawn out of the fiery furnace, swung round by means of the crane by which it has been suspended, and brought to bear on a large anvil. The men arrange themselves in a circle around the heated mass; and, guided by a foreman, they wield their ponderous hammers of sixteen or twenty pounds weight, and produce a rough music by their equal-timed blows: they are 'harmonious blacksmiths,' though perhaps not belonging to Handel's corps. Mr. Samuel Ferguson, in his noble poem, 'The Forging of the Anchor,' has some lines which vividly present this picture:—

'The roof-ribs swarth, the candent hearth, the ruddy lurid row
Of smiths, that stand, an ardent band, like men before the foe;
As, quivering through his fleece of flame, the sailing monster, slow
Sinks on the anvil—all about the fiery faces glow—
"Hurrah!" they shout, "leap out—leap out;" bang, bang, the sledges go:
Hurrah! the jetted lightnings are hissing high and low,
A hailing fount of fire is struck at every crushing blow;
The leathern mail rebounds the hail; the rattling cinders strow
The ground around; at every bound the sweltering fountains flow;
And thick and loud the swinking crowd at every stroke pant "ho!"'

But this was in the old times. If we now visit the Government Anchor Smitheries, such as that in Devonport Dock Yard, we find that steam has driven away something of the old picturesqueness—replacing it by a grandeur of its own. The anchor-shaft is no longer buried in a mere heap of blazing fuel, but is heated in a properly constructed furnace; the bellows are no longer worked by hand, but by the powerful blast of a steam-engine; the forgers need no longer to confine their operations to one small length at a time, for a much greater length can now be managed before it cools down too low; and the circle of anchor-smiths no longer wield their hammers, and expend their strength in blows which were once called powerful but which are now deemed puny. A steam-giant has come amongst them. Mr. Nasmyth's steam-hammer is a contrivance in which a powerful hammer or weight is allowed to fall by its own gravity, but is drawn up by the operation of steam-power; and this alternation of rising and falling occurs several times in a minute—much faster indeed than a man could wield a sledge-hammer. The white-hot anchor-shaft is placed upon an anvil immediately beneath this steam-hammer; and the blows which follow are so powerful and so quickly repeated, that the heated mass becomes forged in a wonderfully short space of time. Let the anchor-smiths group themselves as thickly as they may, and wield hammers the heaviest that human muscles can command—they cannot approach the amount of work which the steam-hammer effects. Even the *Hercules* which formed an intermediate stage between the sledge-hammer and the steam-hammer, and which consists of a heavy mass of iron worked by ropes, must yield in efficiency to Mr. Nasmyth's remarkable machine.

ANCHO'VY is a genus of fish, abundant in the Mediterranean and along the coasts of Spain, Portugal, and France. It occurs also on various parts of our coast, as Hampshire, Cornwall, Wales, &c. They vary from four to seven inches in length. The anchovy has been celebrated from the earliest times, and a sauce or condiment called garum prepared from it was held in high estimation among the Greeks and Romans. In preparing this fish for use, the head and viscera are removed, otherwise the pickle would be intensely bitter; the anchovy was in fact once supposed to have the gall in its head. A fish called the *sardine*, common in the Mediterranean, and belonging to the same genus, is frequently mixed with real anchovies, or even sold salted and barrelled as the genuine fish. The sardine may be known by its long taper form, its dark brown colour, and pale flabby flesh.

A large trade is carried on in the preparing of what are termed *British Anchovies*, especially for making anchovy paste or sauce. The humble sprat is made to do duty for the anchovy. According to the receipt given by Mr. Cooley, two pounds of salt, three ounces of bay-salt, one pound of saltpetre, two ounces of prunella, and a few grains of cochineal, are pounded in a mortar, and then laid in a stone pan or anchovy barrel, layers of sprats alternating with layers of the composition. The whole are then pressed down hard, and kept covered close for six months; after which they are ready for use, and 'really produce a most excellent flavoured sauce.'

ANCHU'SA, the botanical name for a genus of plants, which besides other species, contains the following two, valuable in the arts and in medicine. The *Anchusa officinalis*, common alkanet or bugloss, is sometimes boiled and eaten. The roots contain a considerable quantity of gum, and when boiled yield a demulcent drink, which was once in repute as a medicine. In China this plant is used as a provocative of the eruption of small-pox. The *Anchusa tinctoria*, Dyers' Bugloss or Alkanet, is cultivated in the south of France for the sake of the root, which yields a fine red colour to oils, wax, and all unctuous substances, as well as to spirits of wine. Its chief use is in colouring lip-salves, ointments, &c. It is however sometimes employed for staining wood and dyeing cotton. It is also used for colouring many of the beverages sold under the name of port wine, likewise the corks used for the bottles in which this fluid is sold.

ANCIENT ART. Our knowledge of the fine arts of the ancients is more considerable than that of their useful or manufacturing arts, chiefly in relation to architecture and sculpture. There will be found, however, scattered under various headings in this Cyclopædia, brief notices of such works of ancient skill as have come down to our knowledge with sufficient notoriety to make them interesting.

ANCO'NA, a seaport town on the Adriatic Sea, is the most commercial place in the Papal States, carries on a considerable trade by sea, and is a free port. Its harbour, which is good, is protected by two moles, the ancient one raised by Trajan, and the modern one with the light-house constructed by Clement XII. Ancona exports wax, silk, wool, and corn. It is the only good harbour on the Italian coast of the Adriatic between Venice and Manfredonia, and is the common point of departure for the Ionian Islands and Greece.

ANDALUCI'A or ANDALUSI'A, the most southern of the provinces of Spain, comprises the former Moorish kingdoms of Seville, Cordoba, Jaen, and Granada. On the northern side of the Sierra Morena the productions indicate a climate like that of the south of France; but southward of that range are found the mastic tree, the kermes oak, myrtles, American aloes, palm-trees, the olive, the banana, the caper, orange and lemon trees, the pomegranate, and other productions of warm climates; and in some spots the sugar cane and cotton grow. The orange and lemon trees, particularly around convents and monasteries, form groves of considerable extent, which in the time of blossoming fill the air with a delicious perfume. Besides all the species of corn and fruit, wine and oil make the bulk of the productions of the soil. Among the wines, the Xerez (or sherry), the Pajarete, Malaga, Montilla, Espera, Bornos, and Tintilla, are the most celebrated.

The rich pastures of the mountains and valleys feed innumerable herds of cattle, among which the bulls have been renowned from the fabulous times of King Geryon. The woods of oak of the Serrania de Ronda, of Cordoba, and Granada, afford nourishment to a multitude of hogs; and the Loma de Ubeda, the Dehesa of Cordoba, and the Cartuja of Xerez, produce the finest breed of horses in the peninsula. The seas and rivers abound in fish, and the mountains in every species of game. The riches of the mineral kingdom are abundant. Sixty-six mines are known, which produce gold, silver, copper, iron, lead, loadstone, coals, vitriol, and sulphur.

ANDERNACH, a small town on the west bank of the Rhine, in Rhenish Prussia, has a considerable trade, chiefly in millstones, which are cut in the neighbouring villages of Ober-Mendig and Nieder-Mendig, in bricks, clay for tobacco-pipes; and in trass, which is sent to Holland. This trass is an indurated volcanic mud, of which a vast quantity is accumulated in the valley of Brohl, five miles north of Andernach. It is extensively quarried, and when pulverized and mixed with lime makes a mortar suitable for constructions under water. Trass is a corruption of the Dutch word *tiras*, which signifies cement. In Andernach numerous pieces of columnar basalt are employed as posts at the corners of streets, &c. The door-posts and side-pieces of almost all the windows are made of the porous lava of which the famous millstones are formed. This material is also used for paving courts and kitchen floors, and has been employed in the construction of some of the oldest buildings in this town as well as in Coblentz.

ANDERSON, JOHN, gratefully remembered in Scotland as the founder of the Andersonian Institution of Glasgow, and one of the earliest promoters of that popular instruction in science which has so greatly elevated the character of British artisans, was born in the parish of Roseneath, Dumbartonshire, in 1726. He was appointed professor of Natural Philosophy at Glasgow in 1760; and not content with the ordinary duty of lecturing, he employed himself indefatigably in studying and exemplifying the applications of science to the useful arts, visiting for this purpose the workshops of intelligent artisans, and exchanging his scientific information for their experimental knowledge. The better to carry out his views of popular education, Anderson commenced, in addition to his ordinary class, one which he styled his *anti-toga* class, for the instruction of artisans and others unable to enter upon a regular academical course, to whom he delivered familiar extempore lectures illustrated by experiments. Mechanics were allowed to attend these lectures in their working-dress. He closed his useful career in 1796. Shortly before his death he devised his whole property to eighty-one trustees, for the establishment in Glasgow of an institution to be denominated Anderson's University, for the continued provision of those facilities for the un-academical classes of his townsmen which he had so long supplied by his own personal exertions. His comprehensive design was for an institution consisting of four colleges, with nine professors each, for arts, medicine, law, and theology; but as the funds proved insufficient for so extensive a scheme, operations were commenced in 1797, on a limited scale, by the appointment of Dr. Thomas Garnett as professor of natural philosophy. His first course of lectures was attended by nearly a thousand persons, of both sexes. In the following year a professor of mathematics and geography was appointed; and, though the institution has never attained the magnitude contemplated by the founder, it has been progressively increased and extended in usefulness, and has been productive of much public benefit. Dr. Garnett was succeeded in 1799 by Dr. Birkbeck, on occasion of his removal to the Royal Institution in London, which was formed on a similar model to that established by Anderson; and Dr. Birkbeck, who introduced a new course of instruction for five hundred operative mechanics, free of all expense, was succeeded in 1804 by Dr. Ure.

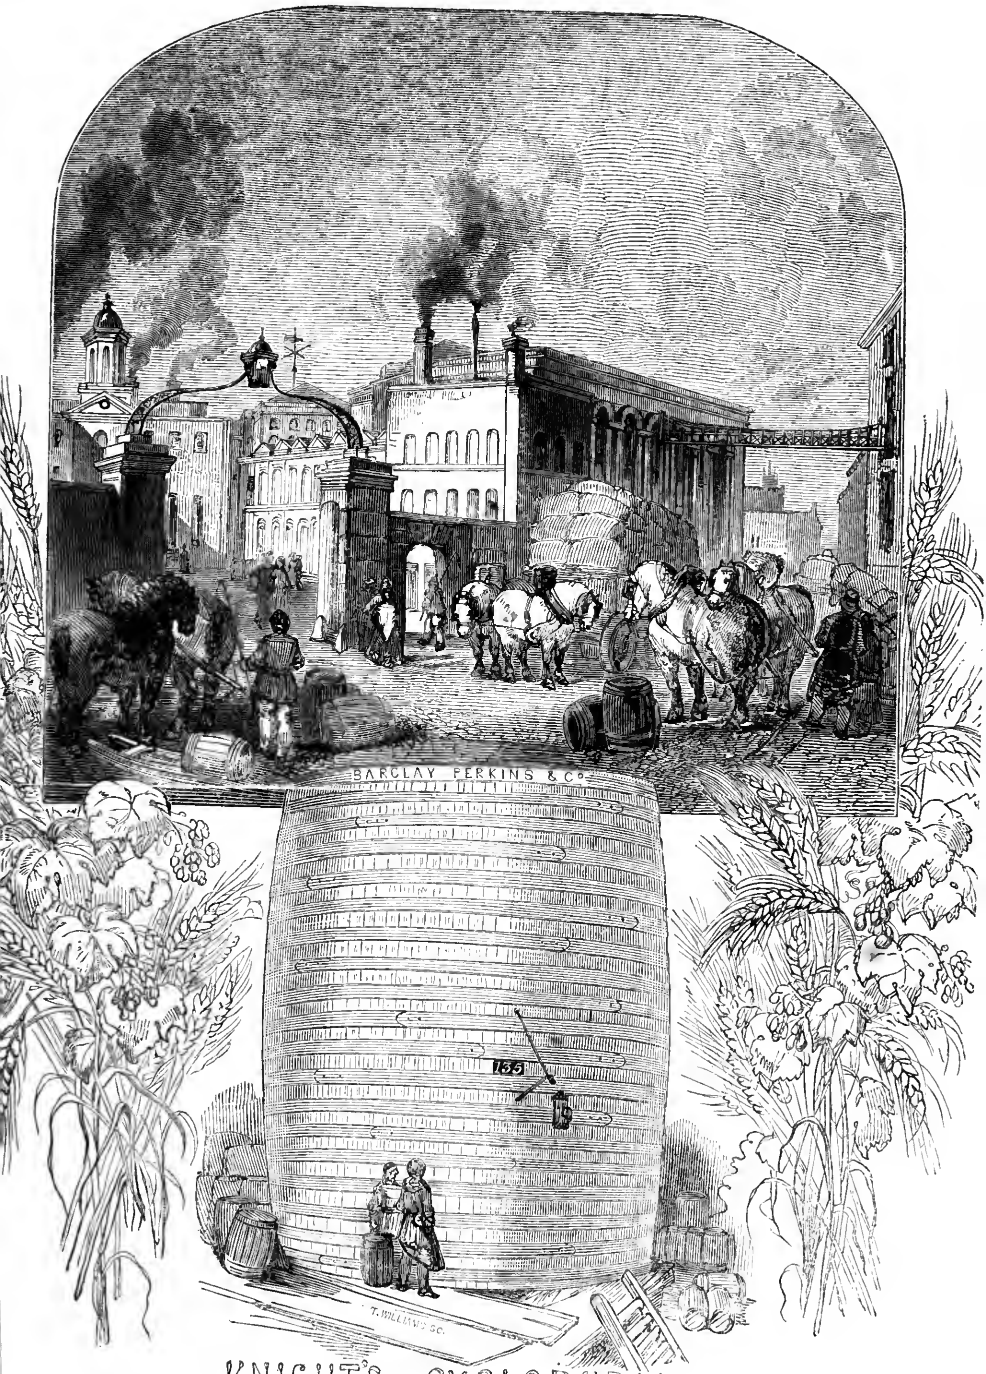
ANDES. This immense American mountain chain is one of the richest mineral storehouses on the globe. Pumice-stone is found to a great extent in many of the volcanoes of the Andes; and volcanic-tuff, which is a stone more or less compact, made up of fragments of hard lava, cinders, and ashes, agglutinated together, covers immense tracts on the flanks of the Andes and on the table-lands. Stone of every description is met with—a storehouse of material ready for the time when manufactures and the arts of civilized life shall find a home in these regions. But it is in metals that the Andes are so especially rich. These mountains have been celebrated for their mines of metal since our earliest knowledge of America. Gold, silver, mercury, platina, copper, and tin, are met with. Gold is found in the form of grains and small rounded lumps, scattered through alluvial soils, which have been derived from the disintegration of rocks containing the metal, and most probably in the form of slender veins. The places chosen for digging into that auriferous soil are called *lavaderos*, because the gravel, sand, and earth, undergo repeated *washings* to separate the heavy particles of gold. The most considerable gold mines are at Petorea, Coquimbo, Copiapo, Pataz, Huailas, Curimayo, Zorata, Antioquia, Choco, and Barbacoas.

Silver is more abundant in the Peruvian than in the Chilian Andes. The richest mines are those of Pasco, in 11° S. lat., which have been worked since the year 1630. Here, as well as in other situations in Peru, the greatest part of the silver is obtained from an ore called in the country *pacos*, which is an intimate mixture of minute particles of native silver with brown oxide of iron. The mines of Chota are also very productive. They are situated in the mountain of Gualgayoc, at an elevation of 13,300 feet, where the thermometer in summer descends every night to the freezing point. The ore lies immediately beneath the surface. But the most celebrated are the silver mines of Potosi, in a lofty mountain. This mountain is perforated in all directions, and it is said that there are not less than 5000 excavations in it, some of them within 120 feet of the top, which is 16,000 feet above the sea-level.

Mercury, in the form of cinnabar or sulphuret of the metal, is met with at Azogué and other parts of the Andes; but the most celebrated, those of Guancavelica, were overwhelmed by incautious mining in 1789. Platina is met with in small quantities in Colombia. Copper and tin are found in the Chilian Andes.

In respect to the commerce of the Andes, little has yet been effected. The passes between the lofty peaks are few in number; and the routes by which the gold and other mining produce reach the ports of shipment are most inefficient. The distance to the Atlantic is in most cases too great to admit of the transfer in this direction: the Pacific ports are for the most part selected.

In a recent number of the *Journal of the*



KNIGHT'S CYCLOPÆDIA OF THE Industry of all Nations.

o. 5.

Franklin Institute, a description is given of a small steam-boat just built at New York for the Andes region. It is 55 feet keel, 12 feet beam, and 5 feet depth of hold. It is to be propelled by two high-pressure engines, of 10-horse power each; with iron paddle-wheels 10 feet in diameter. It is built in separate pieces, all carefully marked and fitted; and for the convenience of carriage, no piece exceeds 350 lbs. weight. It is to be taken by ship to Lima, and the pieces transported on the backs of mules to Lake Titicata, one of the highest lakes on the surface of the globe, in the midst of the Andes. The lake is 140 miles long, and the shores are well timbered; and it is expected that much traffic and commerce will ensue from the establishment of steam navigation there. The pieces of the vessel will be fitted together on the shores of the lake; and if the enterprise succeeds, a larger steamer will be sent out in a similar manner. The surface of Lake Titicata is no less than 12,795 feet above the level of the Pacific; and some parts are nearly 1000 feet deep.

ANDREASBERG, a town of 4000 inhabitants, in the mining district of the Upper Hartz, in the kingdom of Hanover, stands at the southern foot of the Brocken, on a hill 1936 feet above the level of the sea. The neighbourhood is rich in mines, yielding silver, copper, iron, cobalt, and arsenic; and these, as well as the spinning of yarn, lace-making, and the rearing of cattle, afford profitable employment to its inhabitants. The shaft of the Sampson silver mine is 2,333 feet deep.

ANEMO'METER, or *wind-measurer*, is an instrument for ascertaining the force of the wind, generally by finding the mechanical effect which it produces on the apparatus. Wolf's anemometer consists of four small sails, like those of a windmill, which turn on a horizontal axis: this axis is connected by wheel-work with another in which is inserted one end of a bar carrying a weight. The wind acting upon the sails causes this bar to turn in a vertical plane; and, when it is in such a position that the weight on it counterbalances the pressure of the wind, the angle which it makes with a vertical line passing through the axis affords a measure of the wind's force.

Lind's anemometer consists of two tubes of glass, each 9 inches long and $\frac{4}{10}$ inch diameter, which are open at their upper extremities, and are connected at bottom by a bent tube only $\frac{1}{10}$ inch diameter. These are partly filled with water, and the wind acting at the open end of one tube depresses the water in that tube and elevates it in the other, until the difference of height becomes a counterpoise to the pressure of the wind. This difference can be ascertained by a graduated scale, and hence may be obtained the dimensions of a column of water whose weight is equivalent to the force of the wind. The velocity may thence be found, observing that the velocities are nearly as the square roots of the resistances, and that on a square foot, the pressure of wind moving with a velocity of 20 feet per second, is 12 ounces.

In Regnier's anemometer, a bar, carrying a wooden plate at right angles to it, protrudes from a box, through a hole, in the front of which it slides. This bar is met by a spring, which resists its further entry, until force is applied against the plate. In the interior of the box, the under side of the bar carries rackwork, which plays on a cog-wheel, the axis of which, passing through a side of the box, carries a hand round a dial-plate. The anterior surface of the wooden plate is presented to the wind, which presses upon it and forces back the bar, carrying the cog-wheel and hand through an angle, greater or less, according to the greater or less impulse of the wind.

Mr. Elliott, an overman at Pensher Colliery, invented an anemometer in 1835, to measure the rate of the currents of air in coal mines, with a view to regulate ventilation. It consists of a case 12 inches high, 12 broad, and 4½ deep. On a dial are two concentric circles; the inner circle being divided into 48 parts, and the outer into 60. The vanes are connected with two indices or pointers, whose axes of motion are in the centres of the circles, like the hands of a watch; the one pointing to the outer circle and the other to the inner. The movement of one index has a certain ratio of velocity to that of the other; and by the aid of a calculated table, the number of rotations of the slower index within a given time is made to determine the velocity with which the air is moving in or past the machine.

Mr. Biram, in 1843, invented an anemometer for a similar purpose. It consists of a wheel one foot in diameter, having ten oblique vanes of thin sheet copper, perforated for lightness, and covered with tissue paper or varnished silk. The vanes are set at such an angle, that the wheel makes one revolution in the time a current of air two feet in length is passing through it. The axle of the wheel carries an endless screw, into which works a wheel having thirty teeth; and an index is fixed on the axle. As each revolution of the wheel is effected by the action of a current or column of air, two feet in length, one revolution of the index will register the passage of 60 feet of air.

Dr. Whewell's anemometer differs somewhat from others in being calculated to measure the *rate* of the wind rather than its force. It gives no absolute measure of velocity in miles per hour; and the rate is relative only to that of any one instrument at different times, not to that of any common or general standard. At the meeting of the British Association in 1846, Dr. Robinson described an alteration which he had effected in this instrument. On a vertical axis are mounted three or four arms, carrying hemispherical cups at their extremities. These cups oppose much less resistance to air acting on the concave sides than on their convexities, and in such ratio that uniform revolution is produced at the rate of one-third of the velocity of the wind. From this measure, which might be made the same for all sizes of the instrument and in all places, the mean velocity of the wind during a given period could always be obtained in miles per hour. It is believed that this principle of uniform adjustment might be usefully applied to many practical purposes, such as the regulation of wind and water-wheels.

Captain Cockburn devised in 1847 a form of anemometer founded on that of Dr. Robinson, but calculated for use on ship-board. It is seven inches high; the diameter of the wings is sixteen inches; there are four cups placed at right angles, attached by arms to a spindle on which is an endless screw, working in the teeth of two multiplying wheels, marked up to 10,000 revolutions. The concave side of each cup is made so as to receive or contain one-third more wind than the convex side.

Osler's anemometer bears some such relation to the older forms, as the aneroid barometer bears to the common barometer: that is, it acts chiefly by the pressure of the air on a spring, rather than by the rise and fall of a liquid in a tube. The spring is not so delicate in its indications, but it is more manageable in yielding *self-registered* observations. In Osler's anemometer, machinery connected with a spring is made to move a pencil over a piece of paper; so as to keep a continuous register of the variations of wind, both in *intensity* and direction. A fine instrument of this kind is placed on the roof of the Royal Exchange, so arranged as to register its indications in a room below. It also acts as a *pluviometer* or rain-guage.

Mr. Goddard's anemometer, somewhat resembling in principle Mr. Osler's, registers no less than twelve classes of phenomena in respect to the wind; viz.: miles of wind blown during a day; miles of wind blown in each direction; miles of wind blown between any two given periods; hour and minute of the strongest wind; hours in which most wind has blown; times and lengths of calms; velocity of wind at any hour; time occupied by the wind going any certain distance at any period of the day; direction of wind at any minute; mean direction; direction of longest continuance; and direction of the greatest passage of wind.

Professor Phillips described to the British Association in 1846 a simple form of anemometer which depends on a well-known principle. When the bulb of a thermometer, covered with cotton wool, is immersed in water and then exposed to the air, a diminution of temperature ensues, consequent on evaporation from the surface; and when the thermometer is moved through the air, or air be blown upon it, the rapidity of evaporation is increased. Professor Phillips took advantage of this principle, to measure the rapidity of cooling by the rapidity of motion in or through the air, or, conversely, to measure the motion by the cooling. He ascertained the amount of diminution of temperature by simple exposure, and then raised the temperature by the heat of the hand to that of the air, and marked by a seconds-watch the rapidity of cooling when the hand was withdrawn. He next repeated the process when the thermometer was in motion, and he was thus enabled to determine the velocity of a railway carriage in swift movement.

ANE'MOSCOPE, is an instrument for determining the direction of the wind; usually constructed by connecting with the spindle of a weathercock the hand of a dial on which the points of the compass are marked.

ANEROID BAROMETER. At the Swansea meeting of the British Association in 1848, Professor Lloyd introduced a notice of the Aneroid Barometer, which had been patented by M. Fontainmoreau in 1844. Instead of acting by the pressure of the atmosphere on liquids, as most forms of barometer do, this instrument depends on the pressure of the air on thin laminæ or diaphragms of some elastic solid substance. The body of the instrument consists of a hollow brass box, with a dial face on the upper surface. Below the dial face is the diaphragm, stretched all across the box. This may consist of a thin sheet of metal, or of glass, or of caoutchouc, or of some other elastic material; but the patentee mentions especially a thin piece of copper sheet, corrugated circularly, so as to yield sensibly to any pressure. The box beneath the diaphragm is so made that the air can be extracted from it; and the diaphragm is then only protected from the crushing pressure of the air by a number of delicate spiral springs, which are fixed to the interior of the bottom of the box, and support the diaphragm. When the weight of the atmosphere increases (equivalent to the rising of the ordinary barometer) the diaphragm suffers an increased pressure, to which the springs allow it to yield to a certain extent; but a lessened pressure allows it to rise again to its normal state. A delicate piece of mechanism, connected with the centre of the diaphragm, becomes moved when the diaphragm either rises or sinks; and this movement is transferred to index hands, which mark on a graduated dial the amount of rise or fall. The graduations are so made as to correspond with the inches and fractions of an inch in the common barometer.

From a communication made to the *Athenæum* (No. 1117), it appears that an Aneroid barometer was carefully compared for several days with the standard barometer at the Liverpool Observatory. The greatest difference was about four-tenths of an inch; the aneroid showing 31·22 inches on an occasion when the standard barometer showed 30·80. The least difference was one-fiftieth of an inch, the quantities being 29·22 (aneroid) and 29·24 (standard). At a high temperature or a high pressure, the aneroid was generally in excess of the standard barometer; at a low temperature or a low pressure they were nearly on an equality.

It is still a question of doubt among scientific men, to what extent the aneroid barometer may be relied on in various seasons and climates. With respect to the originality of the invention, it is known that something nearly analogous was suggested long ago. The more ordinary instruments for this purpose are described under BAROMETER.

ANGEL, a piece of money anciently coined and impressed with an angel. The angel was originally a gold coin of France, where it was first coined in 1340. It appears to have been introduced, with its minor divisions, the half angel and the quarter angel, into England by Edward IV., in 1465. Charles I. was the last English sovereign who coined the angel. The device on the obverse was the figure of St. Michael standing upon a dragon, and piercing him through the mouth with a spear. The reverse had a ship, with a large cross for a mast, with the royal arms in front. The obverse had the king's titles surrounding the device.

ANGELICA, yields a candy, an extract, a tincture, and an infusion, all useful in medicine. The candy is prepared by boiling the fresh stalks in water, then steeping them for a time in boiling hot syrup, and lastly taken out and dried. The extract, the tincture, and the infusion are obtained in the modes usually adopted for those preparations.

ANGELO BUONARROTI, MICHEL. This great painter, sculptor, and architect, was born in 1474, died 1563. It is not within the objects of this work to enter into minute details of his life, or any critical account of his works. We confine our notice to the mention of the two greatest monuments of his talents, in departments more immediately connected with what we are accustomed to term the industrial arts. Pope Julius gave orders to Michel Angelo to paint the vault of the Sistine Chapel. He most earnestly endeavoured to decline the task, and even alleged that he thought Raffaelle better qualified to perform it; but Pope Julius allowed no impediment to stand in the way of his will, and Michel Angelo, finding himself without an alternative, and impressed with a sense of the vastness and grandeur of the task, commenced his cartoons. He invited from Florence several artists distinguished as painters in fresco, a mode of practice in which he was then inexperienced, and the roof of the chapel was commenced by these assistants, under his direction; their execution, however, fell short of his expectations, and entering the chapel one morning he dismissed them all, threw their work from the walls, and determined on executing the whole himself. Having advanced to the third compartment, he had the mortification to find his labour frustrated by the bad quality of his materials, in which fermentation had taken place, and in utter disappointment he renounced the undertaking. The pope, being made acquainted with this misfortune, sent to him his architect, San Gallo, who investigated the cause of the failure, and taught him how to correct it. Thus reassured he proceeded, and the pontiff hearing at length that the ceiling was half completed, could control his impatience no longer, and ordered the chapel to be opened for his inspection. Many other persons found admission, and among the rest Raffaelle d'Urbino, who then first became acquainted with Michel Angelo's powers as a painter. Struck with admiration he immediately changed his own style, and thanked God that he had been born in the same age with so great an artist. The work was now carried forward without interruption, and the whole was completed within one year and eight months from the time of its commencement; an achievement which, whether we consider the magnitude and sublimity of the performance, or the almost incredibly short time in which it was executed, is unparalleled in the history of art. The effect of the whole work is adapted with admirable accuracy to the vast height at which it is seen, and it is impossible to contemplate it without reverence and astonishment.

To a design which Michel Angelo made at the beginning of his career for the monument of Julius II., we are indebted for the magnificent church of St. Peter. The monument was too vast for the old church, and the pope determined it should be rebuilt. The monument was finished upon a smaller scale, and placed in another church. But St. Peter's was created. The career of Michel Angelo is an example of the splendid results produced by great powers in conjunction with great opportunities. On St. Peter's he was occupied for the last twenty years of his life. As he had occasion, among the number of persons employed in the undertaking, to promote some and dismiss others, he was beset by cabals, and harassed by opposition; and machinations were even employed to deprive him of his office: but he was uniformly supported by the pontiffs, especially by Julius III., who regarded him with profound respect and veneration. For this great work he constantly refused any remuneration, declaring that he dedicated that service to the glory of God. Old age came upon him, not unaccompanied with the physical infirmities which belong to it, but he retained the vigour and alacrity of his mental faculties to the close of his long life.

ANGERS, a town in the French department of Maine-et-Loire, has considerable manufactures of sail-cloth, camlet, serge, handkerchiefs, hosiery, &c; and there are establishments for bleaching wax and refining sugar. Besides the articles from their own factories, the inhabitants carry on a trade in the agricultural produce of the surrounding district, corn, wine and brandy, flax, hemp, wax, honey, and dried fruits. The neighbourhood is famous for its nursery gardens, and especially for its extensive slate-quarries.

ANGLE. Without entering into the science of Geometry, which does not come within the scope of the present work, a few practical details concerning angles may be useful.

An *angle* is the opening of two lines; *rectilinear*, of two straight lines; *curvilinear*, of two curves; *mixtilinear*, of a straight line and a curve. But in truth angle always means rectilinear angle; and when a curve enters, its tangent is the straight line which is used in determining the angle.

A *right* angle is half the opening of a straight line and its continuation: an *acute* angle is that which is less than a right angle; an *obtuse* angle is that which lies between one and two right angles. *Complemental* angles are two which together make a right angle; *supplemental* angles are two which together make two right angles. When lines meet and make a pair of angles, the one less than two right angles is called *salient;* the other, greater than two right angles, is called *re-entrant* or *re-entering.* For salient and re-entering (which are borrowed from fortification) *direct* and *retroflected* have sometimes been used.

The angles which two lines make with the same part of a third, on opposite sides of it, are called *alternate.* Two lines which cross one another make two pair of *vertically opposite* angles. The angles made by adjacent sides of a figure are called *internal;* those made by any sides with adjacent sides produced are *external.* When the angular point is the centre or on the circumference of a circle, the *angle* is said to be *at* the centre, or *at* the circumference. Beginners often confound the angle with the angular point.

A *spherical* angle is made by two circles (usually great circles) of a sphere. When the circles meet at the pole of the equator, and one of them is the meridian, the angle is an *horary* or *hour-angle;* and when neither is the meridian, the angle is frequently called *horary.* The *angle of position* of a star is that made by the circles drawn to it from the poles of the equator and ecliptic. The angle of *elevation* is the angle made by a line drawn from the eye to any object with the horizontal line which is in the same vertical plane as the first line; but when the object is below the horizon, the term is angle of *depression.* When lines are drawn from two points to a third, those two points, and also the line joining them, are said to *subtend* the angle which is made at the third point. The angle which two objects subtend at the eye is their angle of *elongation.* The *angle of the vertical* is a name given to the angle which a line drawn to the spectator's zenith makes with the radius of the earth produced: it is taken as nothing when the earth is supposed to be a perfect sphere.

When one line falls upon another, the angle of *incidence* is the acute angle which the incident line makes with the perpendicular to the other. When the incident line is thrown off again on the same side as that from which it came, the acute angle made with the perpendicular is called the angle of *reflexion;* when on the opposite side, the angle of *refraction.* These terms are nearly confined to optics.

A *dihedral* angle is the opening made by two planes: it is measured by a rectilinear angle, namely, that made by two lines drawn in the two planes perpendicular to their common intersection. A *solid* angle is said to exist when three or more straight lines, not in the same plane, meet at a point.

In measuring angles, a circle is considered as the curved boundary of four right angles. This is divided into 360 degrees (°), each of which is divided into 60 *minutes* ('), and each minute into 60 *seconds* ("). Formerly, the second was divided into 60 equal parts called *thirds*, and so on; but it is now customary to use the tenths, hundredths, &c., of seconds. The present table therefore stands thus:

A whole revolution $=360°=21600'=1296000''$
A right angle $= 90°= 5400'= 324000''$

Degrees.		Minutes.		Seconds.
1	=	60	=	3600
		1	=	60

In the attempt to effect a universal change of weights and measures which followed the French Revolution, the circle was divided into 400 degrees, each degree into 100 minutes, each minute into 100 seconds, and so on. This innovation obtained only a partial introduction, and is now entirely abandoned. When used, it is customary in this country to distinguish the French degrees by the name of *grades*, and to denote one grade by $1^{gr.}$ The convenience of this method, from its close affinity with the decimal system, is certainly great: for example, grades and decimals of grades, such as $12^{gr.}$ 1329 are converted into grades, minutes, and seconds, by mere separation of the figures: thus, $12^{gr.}$ 13' 29".

$1^{gr.}$	is 0°·9	or	54'	or	3240"
1'	„ 0·009	„	0'·54	„	32"·4
1"	„ 0·00009	„	0'·0054	„	0"·324

ANGLESEY, or ANGLESEA, the most northern county in Wales, is rich in minerals. The Mona and Parys copper mines are noticed under AMLWCH. Lead ore, rich in silver, has been found also in Parys Mountain. Limestone ranges traverse the island; marbles, both white and variegated, are procured; mill-stones are quarried at Redwharf and Penmon; and there are coal-mines at Malltraeth, but they do not appear to have been worked with much success.

This island-county is noteworthy in an engineering point of view, as being placed in connexion with the rest of Wales by Telford's beautiful Menai suspension-bridge, and by Stephenson's still more wonderful Britannia Tubular Bridge, just now (1850) completed.

ANIMAL FOOD, PRESERVATION OF. [ANTISEPTICS].

ANIMAL STRENGTH. The subject of animal strength will continue to be of much importance as long as it shall be found necessary to employ men or animals, either in conveying burdens or in giving motion to machinery; since by it the employer is enabled to ascertain what is the greatest quantity of useful work which may be obtained from such agents without subjecting them to a degree of fatigue which might in time prove injurious to their health or bodily powers.

With respect to men, Coulomb found that when a man travels unloaded on level ground he can walk 31 miles daily. Now, assuming the weight of a man to be 160 lbs., we have 160×31 or 4960 for the measure of his strength or the quantity of action, which is, consequently, equivalent to that of a machine capable of carrying 4960 lbs. to a distance of 1 mile, or 1 pound to a distance of 4960 miles in one day.

He found also, from a mean of the work done by the porters of Paris, that with a burden equal to 128 lbs. a man can walk 9·72 miles in a day, from which it follows (the weight of a man being 160 lbs.) that the quantity of action is $(160+128)\times9.72$, or 2799. If the weight of the man be not included, the quantity of action is $128\times9{\cdot}72$, or 1244; and this is to be considered as the useful effect. Subtracting 2799 from 4960, we have 2161 for the measure of the action lost in consequence of the burden; but the useful effect, which in the first case was nothing, is in the second expressed by 1244.

By means of a formula, which was given by Euler, with the data afforded by these experiments, it is found that 272 lbs. constitute the greatest burden which a man of average strength can support, and under which he cannot move. It is found, moreover, that the useful effect is at a maximum when a man is loaded with 121 lbs.: under this burden he can walk $10\frac{1}{4}$ miles, nearly, in a day; and consequently the greatest useful effect is expressed by 1280.

Coulomb further determined, that when a man ascends a convenient flight of steps unloaded, the vertical heights of all the ascents during one day being added together, were equal to 1·82 miles; the quantity of action may therefore be expressed by $160\times1{\cdot}82$ or 291, as if the action were equivalent to that of a machine which could raise 291 lbs. to the height of 1 mile vertically, or 1 lb. to the height of 291 miles during a day. When loaded with 150 lbs. the vertical height ascended was 0·494 miles: the whole quantity of action is, therefore, in this case $(160+150)\times0{\cdot}494$, or 153, while the useful effect is $150\times0{\cdot}494$, or 74; that is, 74 lbs. raised 1 mile vertically.

It is remarkable that, from the result of Coulomb's experiments on the power of men ascending steps, both the greatest weight which a man can carry without moving, and the weight which he should bear to render his useful effect a maximum, are nearly the same in this case as they were found to be from experiments made with burdens carried on level ground.

Coulomb has also made experiments to determine the quantity of action in the case which most generally occurs when heavy goods are carried in towns, viz., that in which a porter, having delivered his burden, returns unloaded for another; and his conclusion is, that, in order to produce the most useful effect in this case, the greatest burden which a man should carry on level ground is 135 lbs., and with this he should walk 7 miles. The quantity of useful action is therefore 135×7, or 945.

It is said that a London porter can carry 200 lbs. on his shoulders at the rate of 3 miles per hour; but this action can only be continued during a short time.

The following statements of the strength of men are taken from Hachette's 'Traité des Machines,' and from other sources; the numerical values being reduced so as to express the number of pounds carried by a man one mile per day of eight hours:—

	lbs.
Drawing a vessel on a canal	753,459
Conveying a load (110 lbs.) in a wheel-barrow (1·018 miles per hour)	896
Drawing a small waggon on four wheels over rather unequal ground	857
Pulling horizontally, the weight being raised by a rope passing over a pulley	378
Rowing in a boat	374
Thrusting horizontally, as at a capstan	368
Turning a winch and axle	159
Digging with a spade	85·3
A soldier marching (12·43 miles) with his arms, &c. (60 lbs.) daily	745

With respect to the horse, the most useful way of employing his strength is to make him draw loads in a cart or waggon; but, even for such work, the estimates which have been made of the quantity of action performed daily are various.

According to Tredgold a horse can draw 125 lbs. at the rate of $2\frac{1}{2}$ miles per hour, which, for one day, would give $125 \times 2\frac{1}{2} \times 8$ or 2500. But Messrs. Boulton and Watt ascertained from trials, purposely made, that a strong horse can draw 125 lbs. at the rate of 3 miles per hour; and the measure of the power of such a horse is 3000, which expresses a number of pounds drawn 1 mile in a day. If this be multiplied by the number of feet in a mile, and the product be divided by the number of minutes in eight hours, the result (=33000) denotes a weight in pounds drawn 1 foot per minute during the eight hours; and that result is now universally adopted as a measure of the power of a horse, and is called *one horse-power*.

The useful effect of a horse when walking in a circle, as in some mills, is considered as equivalent to........................	800
A horse carrying a soldier with arms, &c. (=200 lbs.), can go 25 miles in a day, which gives..	5000
An African dromedary carrying only his rider (160lbs.) can go between 7 and 8 miles per hour during nine or ten hours, which gives $160 \times 7\frac{1}{2} \times 9\frac{1}{2}$, or	11400
An Asiatic camel will carry burdens weighing from 500 to 800 lbs. (suppose 600) at the rate of $2\frac{1}{2}$ miles per hour. This, for a day of eight hours, gives $600 \times 2\frac{1}{2} \times 8$, or	12000

The velocity of a horse in walking is estimated at $5\frac{1}{2}$ feet per second, or $3\frac{3}{4}$ miles per hour; in trotting 12 feet per second, or $8\frac{1}{5}$ miles per hour; and in galloping 18 feet per second, or $12\frac{1}{4}$ miles per hour.

ANIMAL SUBSTANCES. Among the most important materials of manufactures, are those which are derived from the animal kingdom. Few persons are aware, unless they have actually been engaged in manufacturing operations, how numerous and varied these materials are. The bounty of nature has placed at the disposal of man so large a number of substances, derived from so large a number of animals, that there is scarcely an article in daily use but can exhibit an application of some such substance, either in its formation or its decoration. The exterior and the interior, the solids and the liquids—all parts of some animals, and numerous parts of many animals, admit of being thus industriously applied.

In the classified list of objects which are admissible to the Industrial Exhibition of 1851, as announced by the Commissioners, the principal materials of manufactures and the arts derived from the animal kingdom are enumerated, and an attempt is made to arrange them into some convenient systematic form. In the first place the whole series is divided into three sections, viz; 1st. *Animal substances used* *as food;* 2nd. *Animal substances used for medicinal purposes;* and 3rd. *Animal substances used in manufactures.*

Almost every part of almost every species of animal serves as food to some variety or other of the human race. The flesh, the eggs of birds, and the milk of mammalia, are obviously the chief forms in which animal food is presented; but there are many other forms to which more or less of preparative process has been applied; such as preserved meats for long voyages; portable soups; concentrated nutriments; consolidated milk; dried gelatine, albumen, and isinglass; caviare, and trepang; sharks' fins; nests of the Java swallow; honey, &c.

The animal substances used in the medicinal art are exceedingly numerous. Those which the Commissioners enumerate as being fit subjects for exhibition, comprise cod-liver and other animal oils; unguents of spermaceti, lard, oil, and various combinations of the three; musk, castoreum, civet, and ambergris, considered as antispasmodics; phosphorus and ammonia, from bones and hartshorn; crabs' eyes (the calcareous concretions formed in the craw-fish), and cuttle-bone, considered as antacids; cantharides, and their essence cantharidine; and iodine, obtained from marine zoophytes and sponge.

But the animal substances used in manufacturing processes, though perhaps not equalling in *quantity* those consumed as food, are far more varied in quality and texture. They are so numerous, that the commissioners have found it convenient to separate this section into five divisions, viz; *Animal substances employed*, 1st. *for textile fabrics and clothing;* 2nd. *for domestic or ornamental purposes;* 3rd. *for serving as agents in the manufacture of other articles;* 4th. *for the production of chemical substances;* and 5th. *for pigments and dyes.* Under the first division come wool, hair, hair bands and ropes; bristles and whalebone; silk from the silkworm, the pinna, and other insects; feathers, down, and fur; skins, hides, and leather; elytra or beetle wings, for ornaments of dress; &c. Under the second division are included bone, horn, hoofs, ivory, tortoise-shell, shagreen, parchment, vellum, quills, pearls, seed-pearls, mother o' pearl, buffalo shells, Bombay shells, black shells, white-edge shells, yellow-edge shells, flat shells, green-snail shells, coral; together with a large number of softer substances, such as sponge, catgut, gold-beaters' skin, bladders, spermaceti, wax, lard, tallows, oils, &c. Under the third division come glue, isinglass, gelatine, bone-black, ivory black, animal charcoal, &c. Under the fourth division are included bones and other substances from which phosphorus, ammonia, cyanides, &c. are procured. Under the fifth division are enumerated cochineal and carmine; dyes from the galls of aphides; gall-stone pigment from ox-gall; lac, in its various forms of stick-lac, seed-lac, lump-lac, shell-lac, lac-lake, and lac-dye; sepia, from the cuttle-fish; essence d'orient, obtained from the scales of the bleak, and used in the manufacture of artificial pearls, &c.

All or nearly all of the above-named substances will be found noticed under their proper headings in this Cyclopædia.

ANISE and ANISEED. There is a genus of plants known botanically by the name of *pimpernella*, which is chiefly interesting as comprising the species of *anise*, the fruit of which is extensively employed as a carminative medicine, and for the purpose of flavouring liqueurs.

The compound spirit of aniseed is made from aniseed, angelica seed, cassia bark, carraways, proof spirit, and water; or (according to another receipt) from oil of aniseed, oil of angelica, oil of cassia, oil of carraway, and proof spirit. It is used as a pleasant cordial. Another cordial made in France, and known by the name of *Ainsette de Bordeaux*, is a compound of aniseed, coriander, sweet fennel seeds, carraway, oil of cassia, proof spirit, &c.

ANIM'E is the name of a yellowish-brown transparent brittle gum, which exudes from a South American tree called the *Courbaril.* It occurs in pieces of various sizes, and often contains numerous insects imbedded in its mass. It can be softened by various means, but it requires a careful process for its liquefaction. It is extensively used by varnish makers, who combine it at a high heat with oils and turpentine.

ANNEALING is a process by which the extreme brittleness common to glass and some metals when cooled suddenly after melting, is avoided or removed. Such brittleness appears to be occasioned by some disturbance in the regular arrangement of the constituent particles in rapid cooling, and is remedied by cooling very slowly and regularly. A pretty example of the effects of non-annealing is afforded by *glass-tears*, or *Prince Rupert's Drops.* These are made by letting drops of melted glass fall into cold water, whereby they become suddenly solidified without annealing; their form resembles that of a pear, rounded at one extremity, and tapering to a very slender tail at the other. If a part of the tail be broken off, the whole drop falls to pieces with a loud explosion.

Glass-houses are furnished with large *annealing-ovens*, in which this object may be attained by the gradual removal of the glass articles from a hotter to a cooler part, or by allowing the heat of the oven to subside slowly. Analogous operations are employed in the manufactures of cast-iron and other metals. Some malleable metals which crystallize on cooling are brittle in their crystalline state, but are rendered tough by heating and rolling. Zinc, for example, though incapable of more than very slight extension under the hammer, without cracking, becomes almost as flexible and tough as copper after being rolled at a moderate heat.

Cast iron may be made malleable, without subjecting it to the process of puddling; this is effected by a sort of annealing. The iron is kept for several hours at a temperature a little below its fusing point, and then allowed to cool slowly.

ANNIHILATOR, FIRE. In addition to the machines noticed under FIRE ENGINE and FIRE ESCAPE, a new mode of attacking the devouring element is Mr. Phillips's *Fire Annihilator.* Mr. Phillips took out his patent in 1849. The materials employed consist of sugar and chlorate of potash, mixed and boiled together into a homogeneous mass. This is placed in a perforated cylinder, within a second perforated cylinder, contained in a third but air-tight cylinder; and the whole put into an outer case. Water is placed in the space between the bottoms of the third cylinder and outer casing; a vertical pipe opens from this space to the space between the second and third cylinders; so that as the metal expands from the application of heat, the water will be forced up the pipe, and made to mingle with the gas generated from the chemical materials, which will afterwards escape through an opening at the top of the case. It is this gas which is intended to act so remarkably upon a burning mass as to extinguish flame.

With this apparatus Mr. Phillips has made many experiments which have attracted a good deal of public attention. A display was made at Vauxhall Gas Works, in Oct. 1849; model houses and ships, filled with combustibles, were set on fire with a view of shewing how rapidly the annihilator could extinguish the flames. The machine is placed where it can be influenced by the heat of the conflagration; and the resulting gas has a remarkable effect in extinguishing flame; but it does *not* extinguish red heat unaccompanied by flame. Experiments were made in the early part of 1850 at Trentham Park, at the Paddington Railway Station, and at the West India Docks; but the annihilator on these occasions scarcely merited the good opinion of its admirers. A 'Fire Annihilator Company' was, however, established. Shortly after this, the Board of Ordnance permitted a brick building to be constructed in Woolwich Marsh, and made to represent as nearly as practicable (without incurring too much expense) a three storied house, which was then filled with cheap furniture. There were near at hand annihilators of various sizes and degrees of power—one so large as to require two horses to draw it; and a day was appointed for having a grand experimental conflagration. The building was set on fire, but the extinction did not take place satisfactorily.

The truth seems to be (so far as has yet been shewn), that in close rooms, or confined spaces generally, the liberated gases of the annihilator may be serviceably used to extinguish flame; but that where there is plenty of access for external air, the action of the machine becomes impaired. So far as the mere setting to work is concerned, it is so easy and simple, that we may hope to find the apparatus available, in a limited if not an extensive degree.

ANNONAY, a town in France on the banks of the Rhone, is celebrated for making the best paper in France; it is also a busy locality for manufactories of silks, woollens, cottons, and leather.

ANNOTTO. [ARNOTTO.]

ANNULET, in architecture, is the small ring or band which enriches the lower part of the moulding of the Doric column, just where it expands from the top of the shaft.

ANNULUS, the geometrical name for a ring. It is sometimes useful to know the area or solid content of a ring of any substance; and this may be done as follows:—To find the surface of a ring, measure the interior and exterior diameters, multiply the sum and difference of these diameters, and multiply this product by 2·4674. To find the solid contents, measure the inner and outer diameters, multiply together their sum and the square of their difference, and multiply by 0·3084.

ANODY'NES, are substances used in medicine for alleviating pain. They appear to be productive of benefit in two ways: first, by rendering the nerves of the part less sensible; and, secondly, by diminishing the violence with which the large vessels propel the blood, when the anodynes are given in sufficient quantity to influence the brain, and through it, by a process extremely complex, which we need not explain here, the contractile power of the heart and arteries. As most of the articles termed anodynes have a powerful influence over the brain, they generally produce sleep, if given in a large dose: hence they are also denominated *hypnotics;* and, from causing insensibility, they are also denominated *narcotics.* The *Anodyne necklaces* (which partake a good deal of quackery) are formed of the roots of hyosciamus, Job's-tears, allspice steeped in brandy, jumble heads, or elk's hoof, to suit the fancies of the prescribers; they are worn with the hope of procuring easy dentition in children, and sleep in fevers.

The substances which are used as anodynes are, with one exception, derived from the vegetable kingdom; they comprise Opium, Henbane, Woody Nightshade, Deadly Nightshade, Prussic Acid, and Carbonic Acid Gas.

ANONA'CEÆ, is the botanical name for an order of plants, different species of which yield the Ethiopian pepper, the custard apple, bark fit for cordage, &c. The trees and shrubs of this order abound in a powerful aromatic secretion, which renders the flowers of some highly fragrant, the leaves of others a grateful perfume, and the dried fruits of many so highly aromatic as to vie with the spices of commerce.

ANSER. [Goose.]

ANT. If the ant is not especially useful to us in furnishing food, or materials for manufactures, he is an instructive artisan whose movements we may watch with profit. Let us view him as a *miner*, a *mason*, a *carpenter*.

The modes in which ants construct their cities differ considerably. The red ant, for example (*Myrmica rubra*), which is common in gardens, makes burrows and chambers under stones, or in the ground under roots, and the spade often disturbs a peaceful colony.

The dusky turf ant (*Formico cèspitum*) selects a tuft of long grass, the stems of which serve as supports to a slight tenement consisting of small grains of earth, clay, and sand, piled up without any other cement than water, or the dew and moisture of the ground, which produces a sufficient degree of adhesion between the particles. The whole forms a little hillock, underneath which are galleries and chambers. The sanguinary ant, common on the continent (*F. sanguinea*), makes a subterranean city, composed of galleries and chambers, excavated in the earth or clay to a considerable depth. Over the covert ways into this labyrinth is placed a thick coping of dry heath twigs and grass stems to defend it from rain and cold.

The yellow ant (*F. flava*) builds mounds, a foot or more in height, and generally in old pastures. They are composed of particles of soil quarried from below, bits of decayed wood, &c., and are generally built during rainy or moist weather, as these ants have no other means than what the atmosphere affords of tempering their materials. These mounds are smooth externally, and contain chambers and galleries.

The nest of the fallow ant, or wood ant, a large species not uncommon in woods and pleasure grounds, presents a rude appearance: externally it looks like a hillock of earth, intermixed with bits of dried twigs, straws, particles of leaves, and as we have seen, even grains of corn, all mixed together, and forming a large coping or protection to numerous chambers arranged in separate stories, some deeply excavated in the earth, others near the centre or even the surface of the hillock; all communicating with each other by means of galleries; various passages open externally, the entrances being closed or left free, according to the state of the weather.

The colonies of the fuliginous or jet ant (*F. fuliginosa*), make their habitations in the trunks of old oaks or willows, in which with their strong mandibles they work out horizontal galleries separated from each other by thin partitions, and all communicating with each other. These excavations often resemble halls supported by multitudes of pillars, rising story above story, and built of ebony, for the wood is invariably stained black, perhaps in consequence of the action of the formic acid, a peculiar secretion found in ants, and which, dissolved in water, serves the purposes of vinegar in Norway, where the ants are collected and steeped in boiling water, and thus is formed diluted formic acid.

With respect to the ants of hotter climates, the wonderful structures which they make have attracted the notice of most travellers. Some rear huge mounds; some construct large edifices in the forks of trees; some glue leaves together so as to form a purse; some excavate the branches of the trees, working out the pith to the extremity of the slenderest twig.

An accurate observer, Dr. J. R. Johnson, remarks, 'I have often been surprised at the ingenuity of these little creatures, in availing themselves of contiguous blades of grass, stalks of corn, &c., when they wish to enlarge the boundaries of their abode. As these are usually met with in the erect position, they are admirably calculated for pillars; they therefore coat them over with a fine paste of earth, giving them, by additional layers, the solidity they judge necessary for the work.'

ANTACIDS, signify medicines used to correct acidity in the stomach. Though hydrochloric acid (formerly called muriatic acid, or spirit of salt) is present in a free state in the stomach during the process of healthy digestion, yet under particular circumstances it is apt to be generated in excess. Other acids are also occasionally evolved in the stomach, probably from the fermentation of the articles, as vegetables and fruits of different kinds, by which the acetic acid is produced, or introduced ready formed, in wines or hard beer, and in certain vegetables, as sorrel, which contains oxalic acid. The most frequent source of acidity is that first mentioned, the secretion of acid by the vessels of the stomach. It is, therefore, dependent upon constitutional causes, or the state of the system generally.

The medicinal means of remedying this state are all alkaline, either the pure alkalies, or some combination of them—such as solution of potash, or carbonates of soda, potash, magnesia, ammonia, or lime. These medicines are called Antacids.

ANTÆ, a term used by architects to designate the pier-formed ends of a wall, as in the terminations of the lateral walls in a Greek temple, where a plain face returns on each side, having some relation in general proportion to the columns with which they compose. The antæ (for the word is used alike in the singular and in the plural) has a moulded and otherwise enriched cap or cornice, and generally a moulded base. The moulded caps and bases of antæ are, in Greek works, generally continued along the flank walls so as to form the cornice and base of the whole wall, and not of the protruded faces of its ends alone. In Roman works, and in modern imitations of both, breaks are often made on the face of a wall with the caps and bases of antæ, but more frequently with those of columns, and these are called pilasters. In classical Greek works, and in the best Roman works, antæ and pilasters are never either diminished or fluted.

ANTALKALIES, are medicines for counteracting the presence of alkalies in the system. Such remedies consist of the various mineral and organic acids.

ANTEFIXÆ, blocks with vertical faces placed along over a cornice in ancient Greek and Roman buildings, to hide the ends of the covering or joint tiles, and their faces are generally ornamented with a flower, leaf, or other enrichment.

A'NTHEMIS. [CHAMOMILE.] The *Anthemis tinctoria* is used in France by the dyers for the sake of a brilliant yellow tint, which is obtained from it.

ANTHOXANTHUM. [GRASS.]

A'NTHRACITE, a black, light, mineral substance, resembling coal. It is also called *blind coal*, and *glance coal*. Its specific gravity is about 1·400; it is slowly combustible, but without flame; and it contains 96 per cent. of pure carbon: it is, in fact, a mineral charcoal. Naphtha may be considered as one extremity of the mineral carbonaceous substances, and anthracite as the other. Tar, petroleum, bitúmen, asphaltum, and the various kinds of coal, form the intermediate members of the series. Anthracite is now much used as a steam-engine fuel. Sir H. De La Beche and Dr. Lyon Playfair, who were commissioned lately by the Admiralty to investigate the qualities of steam-coal for the navy, have pointed out the many useful qualities of Anthracite. [FUEL]. Small quantities of Anthracite are found in the primary strata of most countries, as, for instance, in the old slate of Cornwall, Devon, and Cumberland, where the appearances led to borings and other works in search of coal. In the south of Ireland anthracite occurs in clay-slate and grauwacke, so thick as to be regularly worked for the purpose of burning the lime of the district; the most considerable collieries have yielded 25,000 tons annually; and all the coal of the province of Munster, with the exception of that of the county of Clare, is of the same sort. It is found in many of our coal-mines, but generally in those situations where the coal comes in contact with clay-slate.

Anthracite, as a fuel for locomotives, has met with but little success. In America, where wood is largely used for this purpose, great desire is exhibited to substitute anthracite for wood; but Professor Johnson communicated a paper to the *Franklin Journal* in 1847, shewing many reasons why it had hitherto not been very successful. There is a want of rapid ignition and lively combustion; the intense local heat tends to destroy the grate-bars, to loosen the rivets, and to blister the iron plates; the ashes of the anthracite fuse into an unmanageable sort of clinker; the sharp angular particles of coal, projected by the violent draught of the furnace obliquely into the ends of the copper tubes, tend to cut the metal near the fire end. Professor Johnson points out modes which, in his judgment, will obviate these several sources of inconvenience, and render the use of anthracite in locomotives desirable.

In a series of experiments made by Messrs. Fairbairn of Manchester, on 280 bars made of different kinds of iron, it was found that anthracite iron, or iron smelted with anthracite instead of other kinds of coal, is superior to other kinds of iron in strength, though not quite equal to some of them in elasticity. The results were communicated *in extenso* to the British Association in 1840.

ANTIDOTES, administered to counteract the effect of poisons, are used with one of three objects, viz., 1, to remove the poisonous substance: 2, to prevent or limit its local effects: 3, to obviate its effects on remote organs, supporting their action by appropriate measures, till the injurious impression has subsided. The first of these is accomplished mostly by mechanical means, such as the cupping-glass or the stomach-pump. The second mode depends on a very intimate knowledge of the chemical elements and action of the poison. The third mode depends on a close study of the physiology of the human system.

ANTI-ATTRITION, is a preparation used to lessen friction in machinery, and also to prevent iron from rusting. It is made by grinding black lead with four times its weight of lard or tallow, and adding a little camphor to the mixture.

ANTI-FERMENT. In the cider-districts a substance under this name is sold for the purpose of correcting fermentation. Mustard seed and clover, or mustard seed and sulphite of lime, are usually the ingredients: they tend to allay the fermentation of cider or perry, or even beer.

ANTI-FRICTION WHEELS. The action of friction or anti-friction wheels in machinery is to diminish resistance by converting what would otherwise be a *rubbing* into a *rolling* contact. Friction-rollers, which are generally of small diameter, are not necessarily fixed upon axles or shafts, but are interposed bodily between the rubbing or sliding surfaces which press upon them; and they may thus be employed to alleviate friction between surface. In some arrangements of mechanism, friction rollers are provided with small axles which do not bear any important strain, but are used chiefly for the purpose of keeping the rollers in their proper place. The wheels of an ordinary carriage are in principle very little other than anti-friction wheels or rollers.

The various applications of anti-friction rotation are very numerous; but they all depend on this principle—that when the surfaces of two bodies are made to pass over each other with a rubbing or sliding motion, their inequalities necessarily meet and oppose each other, and thereby cause both resistance and wear; but if rollers or wheels be applied between them, instead of the inequalities of the roller being dragged against those of the surface upon which it rolls, they are successively laid upon (so to speak) and lifted up from them.

ANTIGUA, is one of the sugar colonies of the British West Indies. The sugar produce of 1846 was 102,644 cwt.; that of 1847 reached nearly double this amount; but 1848 proved a deficient year. A considerable quantity of cotton was once produced in this island, but the culture has been discontinued. If the experiment now being made in Jamaica should, however, be successful, cotton-planting may again be attempted in Antigua. Antigua took British produce and manufactures, in 1849, to the value of 70,194*l*.

ANTILOGARITHM, as used in this country, means the *number to the logarithm*. Thus, in Briggs's system, 100 is the antilogarithm of 2, because 2 is the logarithm of 100. [LOGARITHM.]

ANTIMONY, a metal sometimes called *regulus of antimony*, occurs, though rarely, native, and is generally procured from the sulphuret, which is the only abundant ore of the metal. When this is heated in contact with iron, the sulphur, on account of its greater affinity for that metal, is separated by it from the antimony, which is consequently reduced to a nearly pure metallic state. Its colour is silver white, lustre considerable, and the fracture fine laminated when pure; but the antimony of commerce is broad laminated. Its specific gravity is about 6·7, and atomic weight 64. When slowly cooled after fusion, it crystallizes in the octahedron or its varieties. When it is exposed to the air, this metal tarnishes, and at a red heat it melts. Fulminating antimony is much employed in fire-works.

Oxygen and antimony may be combined in several modes and in different proportions. There are many ways of producing the *sesquioxide of antimony*, the composition of which is —antimony 2, oxygen 3. This oxide is a dingy white powder, insoluble in water, but it is dissolved by dilute nitric acid, and by strong nitric acid is converted into antimonious acid. Muriatic acid also readily takes it up; the same effect is produced by bitartrate of potash, and the solution on cooling deposits octahedral crystals, which have been long known and employed in medicine under the name of *tartar emetic*, or *tartarized antimony*. It is soluble also in potash, soda, and ammonia. A second compound is the *deutoxide*, or *antimonious acid*, containing antimony 1, oxygen 2. This acid is neither fusible nor volatile at a red heat. Its saline compounds are termed *antimonites*, as antimonite of potash, &c. If it be fused with this alkali, the salt formed dissolves in water, from which the acids throw down a white precipitate of antimonious acid combined with water. A third compound of oxygen and antimony is the *peroxide*, or *antimonic acid*. It is a pale yellow powder, consisting of antimony 2, oxygen 5. Its action on the animal economy is but slight. Antimonic acid is tasteless and insoluble in water.

Chlorine and Antimony unite to form two compounds. The *protochloride*, or *sesquichloride* sometimes called *butter of antimony*, is composed of chlorine 3, antimony 2. It is a soft and nearly colourless solid. At a moderate heat it liquefies, and it absorbs moisture from the air. From it is prepared the submuriate of antimony, formerly employed in medicine under the name of *pulvis Algarotti*. The other compound is a *perchloride of antimony*, consisting of chlorine 5, antimony 2. It is a colourless or slightly yellow fluid, has a strong disagreeable smell, and emits white fumes. It attracts moisture from the air, and when mixed with water it is decomposed, and converted into muriatic acid and antimonic acid.

Bromine and Antimony form *bromide of antimony*. At common temperatures it is solid, colourless, crystallizes in needles, attracts moisture from the air, and is decomposed by water. It melts at about 206° Fahrenheit, and boils at 518°. *Iodine* also combines with antimony to form an iodide.

Sulphur and Antimony combine to form several compounds. The chief of these is the *sesquisulphuret*, or *crude antimony*, which is the principal ore of the metal. It is found in many parts of the earth; it is of a lead gray colour, possessing considerable splendour, and is met with compact, in acicular crystals, and in rhombic prisms. It is composed of sulphur 3 atoms, antimony 2 atoms. It is much employed in preparing metallic antimony, glass of antimony, crocus of antimony, James's powder, and some preparations in the London and other pharmacopœias. It is soluble in a hot solution of potash or soda; on cooling, an orange red substance is deposited, called *kermes-mineral;* this was formerly much used in medicine. When an acid is added to the remaining cold solution, a further portion of a similar precipitate is formed: this is sometimes called the *golden sulphuret of antimony*, and in the 'London Pharmacopœia,' *sulphuretum antimonii præcipitatum*.

The only salt of antimony, strictly speaking, of any great importance, is the double tartrate of potash and antimony, usually termed tartar emetic, or tartarized antimony—the *antimonium tartarizatum* of the 'London Pharmacopœia.' Of all the preparations of antimony this is the most valuable. The Pharmacopœias also contain a preparation in imitation of James's powder, called *pulvis antimonialis*.

Antimony is susceptible of combining with all metals. It makes them very brittle. The principal alloys of antimony are that with lead, employed as *type metal*, and the alloy of antimony and tin, used for plates on which music is engraved.

It has been recently suggested, by Mr. Forrest of Liverpool, that antimony would be a good substitute for lead in the manufacture of white paint. He considers that the oxide of antimony is usually cheaper than white lead, that it is not so apt to lose its colour, and that an equal weight of paint will spread over a much larger surface.

Antimony sells at the present time in the London market at 44*s*. to 60*s*. per cwt.

ANTI'PAROS, a small island in the Grecian Archipelago, is interesting in an artistic point of view for the exquisite white marble which it yields. Of this material consists the famous grotto, which is 120 yards long, 113 wide, and 60 feet high; it is an immense arch of white marble, from the roof of which depend large stalactites, 10 feet long and as thick as a man's waist, with festoons and leaves of the same substance; the floor is rough and uneven, with various coloured crystals and stalagmites rising up; and in the midst is one 20 feet in diameter, and 24 feet high. When lighted up, the whole presents a most brilliant and magnificent scene, but the smoke from the torches of the numerous visitors has somewhat dimmed its effulgence.

ANTI'PODES, as a term indicating the inhabitants on two exactly opposite points on the globe, is only interesting to us here so far as it concerns *climate*. Two *antipodal* points of the earth have the same number of degrees of latitude, one north and the other south, unless one of the points be on the equator, in which case the antipodal point is the opposite point of the equator. Their longitude differs by 180° or 12 hours, if we reckon longitude all round the globe; but if we use east and west longitude, the two longitudes must together make up 180° or 12 hours, one east and the other west. We here insert, in opposite columns, the names of a few places which are nearly antipodal.

London	Antipodes Island, S. E. of New Zealand.
Nankin	Buenos Ayres.
Bermudas	Swan River.
Quito	Middle of Sumatra.
Azores	Botany Bay.

Antipodal places have the same climate, so far as that depends merely on latitude; but have all the seasons, days and nights completely reversed. Thus, noon of the longest day at the Bermudas is midnight of the shortest day at the Swan River. The remark as to the seasons of course does not apply to antipodal places on the equator.

ANTIQUES. This term properly refers to works of Grecian art in sculpture, bas-relief, engraving of gems, medals, &c. As these arts flourished in the states of Greece, and also under the Roman Empire (though most probably they were always successfully cultivated chiefly by Greeks), it is not possible to find any precise chronological limits that shall determine whether a work of art belongs to the *antique* or not. Still, as there was under the Roman Empire a great and progressive deterioration in the arts above alluded to, until in more recent times they have been again improved, it is clear that many works of considerable antiquity cannot be classed under the head of *antiques;* for by the term antiques we understand, in general, works that have decided merit, and may serve as models for imitation; or they are at least works of art that serve to illustrate and explain those ancient authors whose writings, by common consent, are allowed to be deserving of study.

ANTIRRHI'NUM. [OILS.]

ANTIS. A portico is said to be *in antis* when columns stand in a line, in front, with the antæ or projecting ends of the side walls of the temple or other building. There is a good example of the portico *in antis* in North Audley Street, London, which forms the entrance to an episcopal chapel.

ANTISCORBUTICS, the remedies, real or reputed, against scurvy. Sea-scurvy formerly prevailed in a very extensive degree. Commodore Anson, in the course of his voyage round the world, lost above four-fifths of his men, and when he arrived at Juan Fernandez, of the 200 men then surviving, eight only were capable of duty. An entire crew has sometimes fallen a victim to it, and the ship been left without a single hand to guide it through the waters. This happened in the case of the Spanish ship Oriflamma, in which the whole crew perished, and in this state she was discovered with the dead bodies on board.

The causes of this disease appear to be exposure to a cold and damp atmosphere, excessive fatigue, badly ventilated sleeping apartments, and intemperance; but none of these causes singly, nor indeed all of them combined, are adequate to produce scurvy, unassisted by some specific cause, which cause is to be found in the *diet.* The diet of seamen during long voyages was formerly merely salted meat and biscuit; fresh animal food or recent vegetables formed no part of it. It was also often deficient in quantity.

Fresh vegetables, vegetable substances, or articles prepared from them, constitute the *antiscorbutics*, or means of preventing and curing sea-scurvy; but they are not all of equal value, some far surpassing others in efficacy. The *lemon* is the most valuable of all. It may be used in various ways; the best is in the form of the fresh fruit, sucked by the patient: but in the absence of this, lemon-juice may be employed, and this is the usual mode in the naval practice. A quantity of it, having a tenth-part of spirit of wine added to preserve it, are supplied to each ship, and in about a fortnight after leaving port its use is begun; each sailor is allowed one ounce of it and one ounce and a half of sugar to mix with the grog, or in many instances with wine, a stated quantity of which is granted in lieu of a certain quantity of spirits, which is withdrawn. This has the effect of almost invariably preventing scurvy affecting any of the crew. The recent admiralty orders (1850) tend to lessen the use of grog and to increase that of lemon-juice.

In addition to the lemon-juice, ships intended to be sent on long voyages are supplied with animal food, so prepared as to be almost as fresh at the end of six years as if it had been killed but a few days and dressed the day previous to its being used. This valuable discovery, which tends so greatly to lessen the inconvenience of a sea-life, as well as to secure the health of those devoted to it, was made by Mr. Appert.

ANTISEPTICS, are the means of preventing those changes in organized matter which are comprehended under the term putrefaction.

All organized substances do not putrefy with equal rapidity, nor under all circumstances. Decomposition goes on fastest in substances which contain nitrogen, and most slowly in substances which contain carbon; hence animal matters putrefy quickly; vegetable, especially of a woody texture, gradually. The conditions necessary for putrefaction to take place are, the presence of air, of a certain temperature, and moisture. If any one of these be excluded, the process is prevented. The moisture may either be external, or it may be the fluids of the body itself. The bulk of the animal frame is made up of fluids, which must either be dissipated by heat, abstracted by some chemical process, or rendered solid by a very low temperature, if we wish to preserve any animal substance in the state most near that of its natural constitution.

The modes of preserving food are either natural or artificial. The natural modes comprehend those which effect this end by abstracting or excluding one or more of the chief agents,—heat, moisture and air; the artificial comprehend those methods of preparation or mixture which produce some chemical change in the substance.

1st. Abstraction of heat. The presence of heat is essential to the exertion of those chemical affinities which take place during decomposition, or constitute the process; abstracting it therefore checks or suspends them. Most articles of food keep better in cold than in warm weather. When the heat has been so completely abstracted that the juices are frozen, *i.e.* become solid, the preservation of the substance is more effectually accomplished. Indeed they may thus be preserved for many years, perhaps ages.

On this principle the Russians preserve their poultry, which they kill in October, and pack in tubs with layers of snow between. The markets of St. Petersburg are supplied with veal brought from a great distance in this state, as well as with whole hogs, sheep, and fish. The Canadians preserve their provisions in the same way.

A precaution is necessary in thawing them; for this end, they should always be put into cold water first. Indeed, in the case of persons buried in the snow, recovery is much more likely to be brought about by plunging the individual into cold water, than by placing him in a warm bed.

This method of preserving food is not applicable to vegetables, but when these are frozen they should also be first put into cold water.

2nd. The abstraction of moisture by heat is employed in drying fish and other animal substances, as beef, bacon, &c., though in these the rapid tendency to putrefaction makes the employment of a certain quantity of salt, &c., necessary, along with the drying, unless the process be carried on with great rapidity, which may be effected by a high temperature and a free circulation of air. Hence in many places, where turf or wood is burnt, hams are hung within the wide kitchen chimney. Drying is also employed for the preservation of vegetable substances, such as grain, hay, &c. It is by this means that botanists preserve plants to form a hortus siccus, or herbarium, and many plants are thus preserved for medical use, but for this purpose a high temperature should never be applied, as it dissipates their active principles.

3rd. The exclusion of sources of oxygen gas constitutes another means of preventing or checking putrefaction; and as the atmospheric air is the most common source of oxygen, we shall limit our remarks to the means of excluding it. The effect of such exclusion is very great. Réaumur varnished some eggs, and found that at the end of two years they were yet capable of producing chickens; and Bomare mentions an instance where three eggs were inclosed within the walls of a church in the Milanese, and when found at the end of 300 years, they had not lost their flavour. Lime-water is the best medium in which to place eggs for long keeping. But more valuable articles than eggs are preserved by this means; and in a condition nearly equal to their fresh state. We allude to the method of preserving animal food and vegetables, promulgated by M. Appert. This consists in boiling the articles (if meat, the bones must be first taken out) to nearly as great a degree as if intended for immediate consumption; they are then put into jars or tin canisters, which must be completely filled with a broth or jelly prepared from portions of the same meat. The jars are then corked and covered with a luting, and the canisters carefully soldered down. After this, they are placed in a boiler of cold water, to which heat is applied till the water boils, and the boiling of which is continued for an hour; the fire must then be instantly extinguished, and the water soon drawn off, but the boiler must not be uncovered, or the bottles taken out, for one or two hours after. By this method meat has been kept sound and well-flavoured for six years and upwards, and has been sent to all parts of the globe. The process of exhausting the air from the vessel which contains the substance to be preserved, and then effectually excluding the atmosphere is a method now frequently used.

A simpler method of preserving animal food for sea-stores is the following:—the meat is cut into slices of four to eight ounces, steeped for five minutes in a vessel of boiling water, and dried on a network at a temperature of about 120° Fahrenheit. The liquid or soup formed by steeping the meat is next evaporated to the state of a thick varnish, to which a little spice is added. The dry pieces of meat are dipped into this gravy, and dried again; and this dipping and drying are repeated two or three times. The meat will in this dry state remain good for a year or two; and must then be cooked in the usual way by boiling, &c.

The natural methods of preserving organized substances are few and simple: the artificial more numerous, as well as more complex. They consist either in causing such changes in the elementary constitution of a body as shall form a new and less destructible article, or in introducing some additional principle which shall hinder the exercise of the natural tendency of the substance to decomposition.

The first set of means constitute the various kinds of fermentation, with respect to which we may remark, that the products of them are not only little disposed to undergo decomposition, but have also a powerful effect in preventing other substances from undergoing it; the most remarkable of these are acetic acid, or vinegar, and alcohol. The formation of sugar, another product of fermentation, is a powerful means of preserving fruits, in which it is formed spontaneously, or to which it is afterwards added. The addition of sugar is practised in forming syrups, jellies, and preserves.

Those parts of plants which contain much carbon last the longest. In trees cut down and exposed to air and moisture, the bark, which contains most carbon, endures after the rest has perished. The seed also contains much carbon, and when seeds are sent from India to England they are always wrapped in recently prepared charcoal. When stakes or piles of wood are to be driven into the beds of rivers or marshes, they are previously charred; and to preserve water sent to sea, the inner side of the cask is also charred.

There are many substances which when added to animal matter prevent for a longer or shorter time their decomposition, such as saltpetre (nitrate of potass), and common salt (chloride of sodium), which last is supposed to act by abstracting the elements of water; certain it is that meat is rendered by salting much drier, harder, less easily digested, and consequently less nourishing. Many aromatic substances have a similar power of preventing putrefaction for a time. They were extensively employed in embalming in ancient as well as modern times, as the Egyptian mummies prove. Oils and resinous substances long resist putrefaction, and preserve other substances from it; bitumen, naphtha, and empyreumatic oils, are examples of this. Russia leather, which is dressed with the empyreumatic oil of the birch, not only does not become mouldy, but also preserves the books which are bound with it. The process of decomposition is greatly hastened by the agency of fungi, such as those which cause mouldiness, and the more formidable destroyers which occasion the dry-rot. The fungi which cause mouldiness are generally prevented from developing themselves by the presence of some aromatic oil; and the others which occasion the dry-rot in timber, may be prevented from developing themselves by the process invented by the late Mr. Kyan. [DRY-ROT.]

ANTONINE COLUMN, a lofty pillar which stands in the middle of one of the principal squares of the city of Rome. It was raised by the senate in honour of the Emperor Marcus Aurelius Antoninus, and in memory of his victory over the Marcomanni and other German tribes. The shaft of the pillar is 13 feet 1 inch in diameter at the bottom, and one foot less at the top; its height, including the pedestal and capital, is 136 feet, of which 13 are under ground; and the statue on the top and its pedestal are 27½ feet more, making the whole height 163½ feet. The capital is Doric. The shaft is made of twenty-eight blocks of white marble. A spiral staircase of 190 steps is cut through the interior of the marble, and leads to the gallery on the top, which is surrounded by a balustrade. The exterior of the shaft is covered with bassi-rilievi placed in a spiral line around, which represent the victories of Marcus Aurelius over the Marcomanni and other hostile nations. The style and execution of these sculptures are inferior to those of the Trajan pillar, which the artists evidently purposed to imitate.

ANTONINUS, WALL OF. This was an entrenchment raised by the Romans across the north of Britain under the direction of Lollius Urbicus, legate of Antoninus Pius, about A.D. 140, and is supposed to have connected a line of forts erected by Agricola, A.D. 80. Julius Capitolinus, the only ancient writer who mentions this rampart, calls it a turf wall (*murus cespititius*). The work was composed of a ditch, a rampart with its parapet, made of materials taken from the ditch, and a military way running along the whole line of the entrenchment at the distance of a few yards on the south side. It extended from Dunglass Castle on the Clyde to the heights above Caer Ridden Kirk, a little beyond the river Avon on the Frith of Forth, or probably to Blackness Castle two miles farther on, though it cannot now be traced so far. In its course are nineteen forts, the eighteen distances between which amount to 63,980 yards, or 36 English miles, and the mean distance from station to station is 3554 yards, or rather more than two English miles. In the position of the forts, the Romans chose a high and commanding situation from whence the country could be discovered to a considerable distance, contriving, as far as circumstances would permit, that a river, morass, or some difficult ground should form an obstruction to any approach from the front. Forts were also placed upon the passages of those rivers which crossed the general chain of communication. From inscriptions discovered in Scotland, it appears that the entrenchment was made by the second legion, by vexillations of the sixth and the twentieth legion, and the first cohort of the Tungri. A very considerable portion of the entrenchment may still be traced. The modern name is Grimes Dyke.

ANTRIM, is one of the chief flax-spinning and linen-weaving counties of Ireland. It contains the flourishing towns of Belfast (the head-quarters of this department of industry); Antrim town, with its smiling bleach-greens in the vicinity; Ballymena and Lisburn, and several other towns which present a marked exception to the poverty of most other parts of Ireland.

ANTWERP, one of the nine provinces of the kingdom of Belgium, is distinguished in an agricultural point of view for the district called the *polders*, which extends along the Schelde, from the neighbourhood of Antwerp city to Zantvliet; it was originally a marsh which was flooded by every tide, its surface being lower than the level of the river at high water. Dykes having been built to keep off the tide, the surface of the marsh was drained by means of water-wheels turned by windmills, and what was before an unhealthy swamp was changed into the richest pasture and arable land. The city of Antwerp has a large commerce, and fine docks and quays to accommodate it. The new quay and the great basin were begun by Bonaparte, and were part of the plan by which he intended to make this city a great naval station. The area of the great basin is 17 acres, and of the small one 7 acres. On each side of the great basin are two careening docks, made during the empire of Napoleon for repairing the ships of war constructed here.

Antwerp is the principal seat of the silk manufactures of Belgium, and is especially famous for its black silks and velvets. It has large manufactures of cotton, linen, lace, carpets, hats, cutlery, and surgical instruments; there is also a bleaching establishment which is worked by steam, several sugar refineries, and other establishments common in large towns. It contains a great military arsenal, dockyards, and an extensive rope-walk. The imports consist principally of coffee, sugar, and other colonial products, cotton stuffs, and other manufactured goods, corn, raw cotton, leather, timber, tobacco, wool, dyestuffs, salt, wines, fruits, &c. The exports consist chiefly of flax, cotton and linen manufactures, refined sugar, glass, zinc, oak-bark, grain and seeds, lace, &c.

ANVIL. The anvil on which the swarthy smith pursues his labours is usually made of iron and faced with steel. It is made of seven pieces, forged separately, and welded together into form. These pieces are the core or body, four corner pieces which serve to enlarge the base, a projecting end with a square hole, and a beak or horizontal cone. The welding of these pieces together requires good workmanship. The steel facing is welded upon the iron in a similar way.

The size, the shape, and the finish of an anvil depend upon the use to which it is applied. Those used by watchmakers and jewellers are small and delicate. Perhaps the largest anvil in the world is that which is placed beneath the ponderous *Nasmyth's hammer* at Sir John Guest's Dowlais Iron Works, Merthyr Tydvil; it weighs 36 tons, and was cast in one piece! The foundation prepared for it was of vast depth and strength.

ANZIN, a village in the neighbourhood of Valenciennes, in the department of Nord, is the seat of the most extensive collieries in France. The pits amount to forty altogether, some of which are more than 1400 feet deep. The coal burns fiercely, and is in demand for purposes which require an intense flame; to this circumstance perhaps may be ascribed the establishment of glass-works and manufactories at Anzin. The number of persons employed in the mines amounts to 16,000, and the annual produce is about 200,000 tons.

A'PATITE, a mineral substance crystallized in the regular six-sided prism, usually terminated by a truncated six-sided pyramid. It has usually a yellowish green tint, and is translucent. In hardness it ranks above fluor-spar, and below feld spar. It is a compound of phosphate of lime with fluoride of calcium. It principally occurs in the primitive rocks, and is found in the tin mines of St. Michael's Mount, Cornwall; in those of Bohemia and Saxony; and in mineral beds met with in Estremadura in Spain.

APENNINES, the great mountain-system of Italy, are not so rich in mineral produce as many other mountain chains. The chief among them, perhaps, are the celebrated marble quarries of Carrara and the pumice of Vesuvius. There is also the peculiar stone called *travertino*, which is a deposit from water holding carbonate of lime in solution, by means of the carbonic acid which is common in spring waters; by exposure to air the carbonic acid escapes, and the carbonate of lime is deposited; such springs abound in many parts of central Italy within the volcanic region. There are vast deposits of this travertino, which is used for building purposes.

APHIS. The genus of insects called by this name is a great torment to the farmer. These insects sometimes make sad havoc with the CABBAGE, the HOP, and the TURNIP, as the reader will find noticed.

APIARY, a place for keeping bee-hives, is usually shielded from wind, but authorities differ much as to the best direction in which it can be placed. [BEE-HIVE.]

APIIN, the peculiar principle of parsley, obtained from it by solution in water. It is nearly insoluble in cold water and alcohol, but soluble in either when heated; soluble in the alkalies, in lime water, in sulphuric acid, and in muriatic acid. Many of its solutions assume a gelatinous state.

APIUM. [CELERY.]

APLANATIC LENS, is a lens which should be capable of so refracting all the rays which, diverging from or converging to any one point in the axis, are incident upon it, that after being transmitted through it they may con verge to or diverge from one other point in the same axis.

A spherical lens cannot, when formed of any known media, be made strictly aplanatic; and it having been found impossible hitherto to execute lenses with surfaces produced by the revolutions of conic sections, mathematicians have investigated expressions for the form under which, with a given refractive index, the aberration of the focus shall be a minimum.

A few details, illustrative of the aplanatic quality in lenses will be met with under MICROSCOPE; TELESCOPE.

APOLLO BELVEDE'RE, a celebrated statue of Apollo, found at Capo d'Anzo, in the ruins of ancient Antium, about 32 miles from Rome, towards the end of the fifteenth century. It was purchased by Pope Julius II., before his elevation to the pontificate; and was placed by him in the Belvedere of the Vatican, whence it derives its present name. It has been said to be the work of Agasius the Ephesian, but no certain indications of the sculptor are to be traced. But it is now pretty well proved that it was made under the emperors, and probably by the order of Nero himself.

APOLLO'NICON, the name given to a chamber organ of vast power, supplied with both keys and barrels, built by Messrs. Flight and Robson, of St. Martin's Lane, London, and first exhibited by them at their manufactory, in 1817. It has 1,900 pipes, the largest 24 feet in length, and 1 foot 11 inches in aperture, sounding the G, two octaves below the first line of the base, the highest giving the A in altissimo, two octaves above the second space in the treble. The number of stops is 45, and these in their combinations afford very good imitations of the various wind instruments used in an orchestra. As a self-playing instrument, the apollonicon is provided with two revolving cylinders, studded like that of a barrel organ. As a keyed instrument, it has five key-boards, of which the largest comprises five octaves. The swell, the compound pedals, and all the accessory arrangements, are on a very complex scale.

APO'PHYGE, a term applied by architects generally to a concave surface lying between or connecting two flat surfaces not in the same plane, and particularly to a slight concavity which is almost invariably found to terminate the shaft of an Ionic or Corinthian column both above and below. The more familiar English term for the same thing is, the *escape;* and in French, the apophyge is termed the *congé*.

APOTHECARIES' WARES. Under this designation the Customs' department give an entry of the quantity and value of the drugs and chemicals exported from England to our Colonies annually. These quantities and values are larger than many persons would suppose. They amounted in 1849 to 22,691 cwt., valued at 116,546*l*. The East Indies and New South Wales were the chief places of destination.

APOTHECARIES' WEIGHTS AND MEASURES. In buying and selling medicines wholesale, avoirdupois weight is employed; but in *dispensing* medicines the pound troy is divided into 12 ounces, the ounce into 8 drams or drachms, the dram into 3 scruples, and the scruple into 20 grains.

The late Dr. Young calculated, that the relations which exist between apothecaries' weight in England and other countries are as follow:—1000 English grains equal 1125 Austrian, 989 Dutch, 981 French, 978 Hanoverian, 958 German, 956 Bernese, 955 Swedish, 925 Spanish, 909 Roman, 864 Portuguese, 860 Neapolitan, 850 Genoese, 824 Piedmontese, 809 Venetian.

Apothecaries' *fluid* measure is as follows:—60 minims one dram; 8 drams one ounce; 20 ounces one pint. A minim of water is almost exactly one drop; and a fluid ounce of pure water is almost exactly equal to an ordinary ounce weight; but this is not the case with liquids either heavier or lighter than water.

APPALACHIAN MOUNTAINS. This important North American mountain chain is chiefly valuable in an economical point of view for its beds of coal. In Pennsylvania there is a vast deposit of coal, associated with sandstones and slates. The coal seems to be of that quality which in Britain is generally called *blind coal* or *anthracite*. One of these coal-fields, in the valley of Wyoming, is 60 miles long by 5 broad; a second is in the valley of the Lehigh river; and others on the Schuylkill, the Susquehanna, and the Lackawanna. Besides these beds of anthracite coal, there are beds of bituminous coal high up in the Alleghanies of Ohio.

Natural springs, extremely rich in salt, are found all along the western slope of the Appalachian system; and from Onondago, in New York, to the southern termination of the mountain system, wherever the earth has been penetrated to any considerable depth, salt water has been found; in some places, where the boring was from 300 to 400 feet, the water rushed up with so much force, as to rise like a fountain several feet above the surface of the ground. Among the mineral products are iron, lead, and gold; but not in large quantity. The trees growing on and near the mountains are the oak, the pine, the hickory, the sugar and other maples, the Weymouth pine, the hemlock spruce, the laurel, the magnolia, the liriodendron, and many others.

APPAREL. In the exports of British and Irish manufactures, numberless small articles are grouped together by the Customs' authorities under the heading *Apparel, Slops*, and *Haberdashery*. The value of this *Apparel*, &c., exported in 1848, amounted to the large sum of 1,512,271*l.* Our best customer was the United States (328,705*l.*), then Australia (308,765*l.*), next British North America (211,889*l.*) then the West Indies (143,249*l.*), the East Indies (115,487*l.*), and the Cape of Good Hope (103,422*l.*)

In 1849 the exports of apparel, &c., to our own Colonies alone amounted to 1,186,832*l.*

APPENZELL, one of the twenty-two Swiss cantons, is worthy of our notice in respect to its industrial features.

Dr. Bowring's Report on the manufactures of Switzerland presents the industry of Appenzel in an interesting point of view. He says that the cotton and linen manufactures form almost the entire wealth of the canton, pay for all the imposts, and keep the canton out of debt. Hand-spinning, both of linen and cotton, had been known for many generations; but the first spinning-machine in Appenzel was put up in 1783. For many years during a recent period England exported about a million lbs. of cotton yarn annually to Appenzel; but the Swiss are now setting up efficient spinning machines for themselves. The factory system, however, is not much acted upon; and it seems therefore probable that England will continue to be able to supply yarn cheaper than the manufacturers of Appenzel can spin it for themselves. The persons chiefly employed are *manufacturers, weavers*, and *embroiderers*. The manufacturer or master undertakes the entire production of the woven goods—in some cases only so much as he and his family can weave; but in other cases as much as a hundred other persons can assist him in producing; they sell their goods either unbleached to the traders at home, or bleached to foreigners. The weavers are employed at their own houses, receiving yarn from the manufacturers, and returning the finished goods. The embroiderers are women and young lads; the merchants buy woven muslins, cause a pattern to be stamped upon them, and give them out to be embroidered—an employment at which the embroiderers earn about eighteen kreutzers (6½*d.*) per day.

APPLE. This fruit, which, from its hardiness and great abundance, combined with its excellent flavour, is one of the most important productions of cold climates, is, in its wild state, the austere crab-apple of the hedges.

England is celebrated for the excellence of its apples, and consequently of its cider, a beverage which perhaps acquires its highest degree of excellence in Herefordshire and the neighbouring counties. [CIDER.]

For *cooking*, the best kinds of apples are the following:—for summer use, the Keswick Codlin and the Hawthornden; for autumn the Wormsley Pippin and the Alfriston: for winter and spring the Bedfordshire Foundling, Dumelow's Seedling, Dr. Harvey, Brabant Bellefleur, and Gravenstein; and for drying, the Norfolk Beaufin. Of all these, the Gravenstein, Alfriston, and Brabant Bellefleur are the best.

Of *dessert* apples, the varieties are endless; but by far the greater part of the local sorts and of those commonly cultivated, is of only second-rate quality. The finest variety of all is the Cornish Gilliflower; no other equals this in excellence, but it is unfortunately a bad bearer. Of those which combine productiveness and healthiness with the highest quality, the six following must be considered the best:—Golden Harvey, Old Nonpareil, Hubbard's Pearmain, Ribston Pippin, Dutch Mignonne, Court of Wick. Finally, the best selection that could be made for a small garden, so as to obtain a constant succession of fruit from the earliest to the latest season, would be the following, which are enumerated in their order of ripening, the first being fit for use in June, and the last keeping till the end of April:—White Juneating, Early Red Margaret, White Astrachan, Sugar-Loaf Pippin, Borovitsky, Oslin, Summer Golden Pippin, Summer Thorle, Duchess of Oldenburgh, Wormsley Pippin, Kerry Pippin, Yellow Ingestrie, Gravenstein, Autumn Pearmain, Golden Reinette, King of the Pippins, Ribston Pippin, Fearn's Pippin, Court of Wick, Golden Harvey, Golden Pippin, Beachamwell, Adam's Pearmain, Pennington's Seedling, Hughes's Golden Pippin, Cornish Gilliflower, Dutch Mignonne, Reinette du Canada, Syke-House Russet, Braddick's Nonpareil, Old Nonpareil, Court-Pendu Plat, Lamb-Abbey Pearmain, Newtown Pippin.

Many different methods of *preserving* apples have been recommended, and almost every one has some favourite plan of his own. A very good method is to allow the fruits, after being gathered, to lie till their superfluous moisture has evaporated, which is what is technically called 'sweating;' the apples should then be wiped quite dry, wrapped in tissue paper, and stowed away in jars or chests of pure silver sand which has been previously dried in an oven. They should always be taken out of the sand a few days before they are wanted, and laid in dry fern or some such substance; they then absorb oxygen, and acquire a little sweetness, which is necessary to their perfection.

Apples are kept in good condition for the London market in the following way. A cool spot is selected, and layers are heaped up—first of straw or paper, and then of apples, alternately, to a height of about two feet: or the alternate layers are placed in baskets, and the baskets piled one on another. For domestic purposes, apples may be preserved by wrapping each in a piece of clean dry paper, placing them in small wide-mouthed jars or honey-pots, piling the pots one on another, and cementing the fissure between the pots with a paste of plaster of Paris. The pots are kept in a cool place; but shortly before using, the apples are placed in a warm room for a few days. Apples may also be preserved by immersing them in bran: each apple being separated from the rest by its envelope of bran. The Americans preserve apples for two or three years, by peeling them, cutting them into eighths, taking out the cores, and drying the rest in the sun or in a kiln until quite hard; when about to be used, the apples are exposed for a few minutes to the action of boiling water.

Apples will yield sugar, by expressing the juice, neutralising the acid with chalk, boiling, clarifying, and evaporating. One cwt. of apples will yield 84 lbs. of juice, from which may be obtained 12 lbs. of crude sugar.

Besides our home growths, the trade in foreign apples is now very large. In 1848 we imported no less than 331,069 bushels; those from British Colonies pay 2*d*. per bushel import duty; from foreign countries 6*d*.

APPRENTICE, signifies a person who is bound by indenture to serve a master for a certain term, and receives, in return for his services, instruction in his master's profession, art, or occupation. In addition to this, the master is often bound to provide food and clothing for the apprentice, and sometimes to pay him small wages; but the master often receives a premium.

The system of apprenticeship in modern Europe is said to have grown up with the system of associating and incorporating handicraft trades in the twelfth century. These corporations, it is said, were formed for the purpose of resisting the oppression of the feudal lords, and the union of artisans in various bodies must have enabled them to act with more effect. The restraint of free competition, the maintenance of peculiar privileges, and the limitation of the numbers of such as should participate in them, were the main results to which these institutions tended. To exercise a trade, it was necessary to be free of the company or fraternity of that trade; and as the principal if not the only mode of acquiring this freedom in early times was by serving an apprenticeship to a member of the body, it became easy to limit the numbers admitted to this privilege, either indirectly by the length of apprenticeship required, or more immediately by limiting the number of apprentices to be taken by each master. In agriculture, apprenticeship, though in some comparatively later instances encouraged by positive laws, has never prevailed to any great extent. The tendency to association indeed is not strong among the agricultural population, combination being to the scattered inhabitants of the country inconvenient and often impracticable; whereas the inhabitants of towns are by their very position invited to it.

Since the twelfth century, apprenticeship has prevailed in almost every part of Europe —in France, Germany, Italy, and Spain, and probably in other countries. It is asserted by Adam Smith, that seven years seems once to have been all over Europe the usual term for the duration of apprenticeships in most trades. There seems, however, to have been no settled rule on this subject, for there is abundant evidence that the custom in this respect varied even in different incorporated trades in the same town.

Neither in Ireland nor in Scotland have the laws relating to associated trades or apprentices been very rigorously enforced. In Ireland the same system of guilds and companies certainly existed; but, as it was the policy of the English government to encourage settlers there, little attention was paid to their exclusive privileges; and in 1672 the lord-lieutenant and council, under authority of an act of parliament, issued a set of rules and regulations for all the walled towns in Ireland, by which any foreigner was allowed to become free of the guilds and fraternities of tradesmen on payment of a fine of 20s. There is no country in Europe in which corporation laws have been so little oppressive as in Scotland. Three years are there a common term of apprenticeship, even in the nicer trades; but the custom is different in different communities.

In England the institution of apprenticeship is of very old date, being probably contemporaneous with the formation of the guilds or companies of tradesmen. The apprentice laws were enacted at a time when the impolicy of such legislation was not perceived. But opinion gradually became opposed to these enactments, and the judges interpreted the law favourably to freedom of trade. Accordingly the decisions of the courts tended rather to confine than to extend the effect of the statute of Elizabeth, and thus the operation of it was limited to market towns, and to those crafts, mysteries, and occupations which were in existence at the time it was passed. And although, in consequence of this doctrine, many absurd decisions were made, yet the exclusion of some manufactures, and particularly of the principal ones of Manchester and Birmingham, from the operation of the act, had probably a favourable effect in causing it to be less strictly enforced even against those who were held to be liable to it.

Apprenticeship, though no longer legally necessary (except in a few cases), still continues to be the usual mode of learning a trade or art, and contracts of apprenticeship are very common. By common law, a person under the age of twenty-one years cannot bind himself apprentice so as to entitle his master to an action of covenant for leaving his service or other breaches of the indenture.

The churchwardens of parishes have long possessed power in respect to apprenticing pauper children; and overseers of the poor possess similar powers.

An indenture is determinable by the consent of all the parties to it; it is also determined by the death of the master. But if there is any covenant for maintenance the executor is bound to discharge this as far as he has assets. By the custom of London, if the master of an apprentice die, the service must be continued with the widow, if she continue to carry on the trade. In other cases it is incumbent on the executor to put the apprentice to another master of the same trade.

A master may moderately chastise his apprentice for misbehaviour; but he cannot discharge him. If he has any complaint against him, or the apprentice against his master, a power is given to punish or discharge the apprentice, and in some cases to fine the master. If any apprentice, whose premium does not exceed 10*l*., run away from his master, he may be compelled to serve beyond his term for the time which he absented himself, or make suitable satisfaction, or be imprisoned for three months. If he enters another person's service, his master is entitled to his earnings, and he may bring an action against any one who has enticed him away.

Except in the case of surgeons and apothecaries, proctors, solicitors, attorneys, and notaries, there is now no apprenticeship required by law in England.

The peculiar transition state, in Germany, between *apprenticeship* and *journeymanship*, is described under Artizans.

APRICOT. This fruit is in this country produced either upon open standard trees, or upon walls with a westerly aspect. The fruit produced upon walls is the finest, but that from standards is by far the best flavoured. Of the kinds that are cultivated upon walls there are only three that are much worth having, namely, the Orange for preserving, and the Moorpark and Turkey for the table; several others are to be met with in nurserymen's catalogues, but they are of little importance.

Apricots may be dried (or, as it is sometimes termed, candied) in the following way. The stones are thrust out with a wooden skewer; the apricots are peeled, rolled in dry pounded sugar, immersed in cold syrup, and heated gradually nearly to the boiling point. They are scalded again the next day, sweetened with sugar, and allowed to drain on a hair sieve. Sometimes they are preserved, with the peel left on; and sometimes they are cut into quarters or eighths before preserving.

A'PTERAL is a term applied to a temple which has prostyles, or porticoes of columns projecting from its fronts or ends, but of which the columns do not extend laterally, and run along the flanks from one end to the other, which would make it *peripteral*. The parallelogrammic temples of the Romans were for the most part simply apteral prostyles, and their arrangement has been much more followed in modern works than that of the Greek temples, which are, with few exceptions, peripteral.

AQUA REGIA, or NITRO-MURIATIC ACID. [Chlorine.]

AQUAFORTIS. [Nitric Acid.]

AQUATINTA ENGRAVING, a mode of engraving which is an imitation of water-colour or India-ink drawings. The inventor, a German artist named Le Prince, was born at Metz in 1723. His method was to sift black resin over a clean copper plate; the resin was fixed by a moderate heat sufficient to make the dust adhere without fluxing or becoming an even varnish: he thus formed a granulated surface, on the plate, usually called a *ground*, which suffered very little from the action of the diluted acid, yet allowed it to corrode very freely in the small spaces left between the grains of the resin. Mrs. Catherine Prestel, also a German, improved much upon the meagre works of Le Prince, and executed several large works with so much success, that little more was found wanting than a ground that would adhere better to the plate and yield a greater number of impressions; this was effected by dissolving the resin in alcohol, and then pouring the mixture over the plate, the quantity of resin determining the coarseness or fineness of the grain. The modern aquatinters have another advantage over their predecessors in using a composition for painting the forms of leaves of trees, or other objects, where the trouble of surrounding the forms by a varnish would be too great. This composition is made of treacle, whiting, and gum. When used, it must be thoroughly dry before the varnish is passed over it; the varnish also must be allowed time to dry; after which, cold water poured on the plate will in a few minutes bring off all the composition and the varnish which had passed over it, leaving the forms perfect, and the ground in those places free to receive the acid again. The remainder of the plate is permanently *stopped out* by a resinous varnish; with this also the margin of the plate is to be varnished, leaving a narrow strip of the ground for trials or tests. The design intended to be engraved is then made on the ground; this is done in the following manner:—The design is first copied on very thin transparent paper, called tracing-paper; between this tracing and the prepared ground on the plate a thin sheet of paper is placed, which has been rubbed over with lamp-black or vermillion, and sweet oil; every line of the design is then gone over with an instrument called a blunt point, with a moderate pressure, and is thus transferred to the ground so securely that the acid cannot destroy it.

Before the acid is poured on the plate, a border or wall of wax (formed of burgundy pitch, bees' wax, and sweet oil), about an inch in depth, is placed round the margin of the plate.

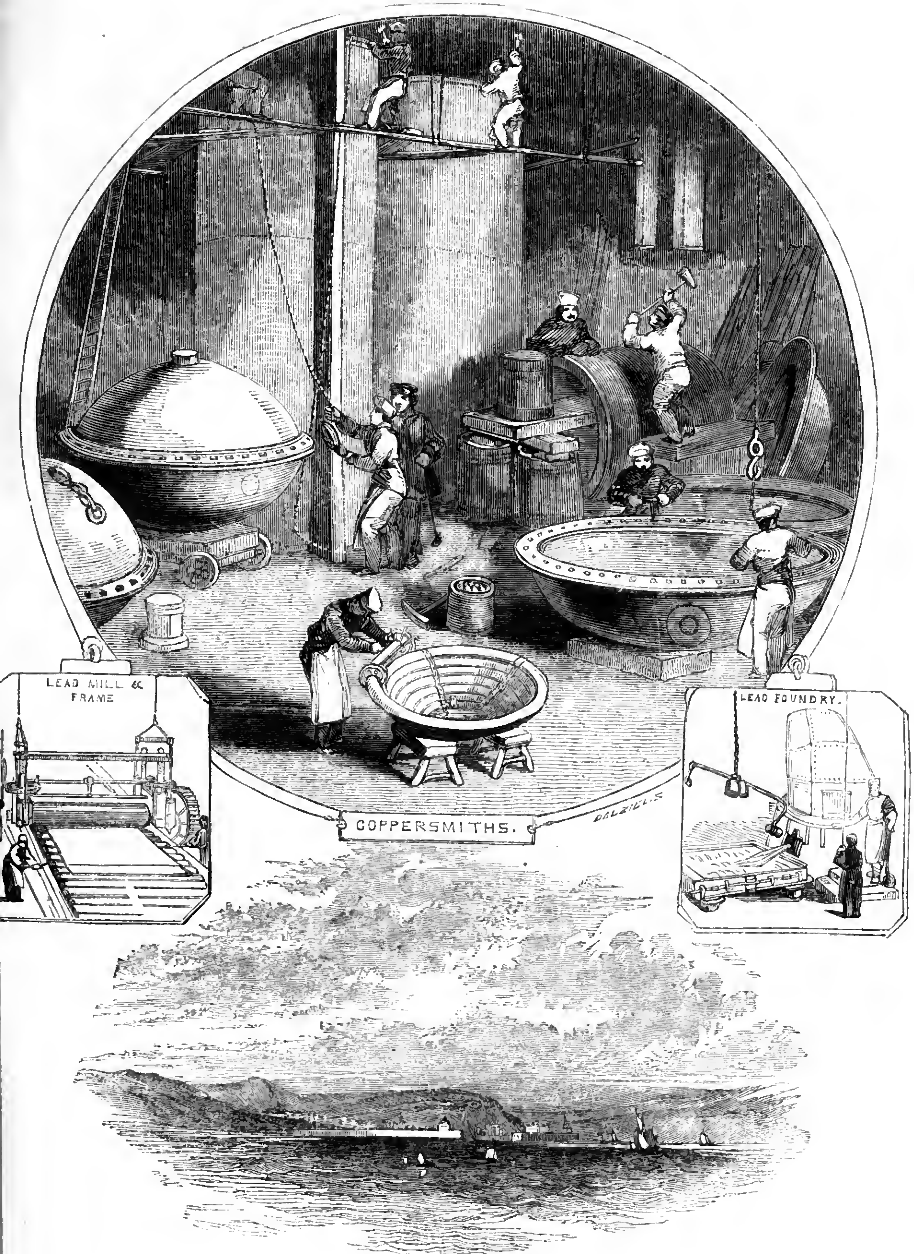
The plate being so far made ready, the completion of the design is resumed by stopping out the highest lights on the edges of clouds, water, &c., with a varnish of Canada balsam, oxide of bismuth, and turpentine. Next pour on diluted aquafortis; let it remain, according to its strength, from half a minute to a minute, then pour it off, and wash the plate three or four times with clean water, and dry it with a clean linen cloth or a pair of bellows. If on trying the strip the tint is found not to be sufficient, repeat the acid for another half minute, and then proceed. The colour of the bismuth varnish must be changed for the second stopping out, by adding a little chrome-yellow, vermillion, or lamp-black, or any other colour that is not destroyed by the acid. The colour is to be changed after each application of the acid, that the engraver may remember in what places he has carried forward his work, what tints have been softened at their edges, &c. The acid should be strengthened a very little after each application. When the ground changes to a gray colour it is beginning to fail, and must be taken off by heating the plate till the bordering wax will lift off; after this, sweet oil is applied to the whole surface, and a brisk heat beneath the plate will bring off all the different varnishes with a linen cloth; then an oil rubber, made of fine woollen cloth, rolled up hard and the end cut off, applied with sweet oil, will take out the stains; tints which are too strong may be softened or even rubbed out. The plate is now cleaned with spirits of turpentine and sent to the printer to prove, after which it is to be exceedingly well cleaned with turpentine, &c., and another ground laid; this should be done in such a manner as to make the grains fall exactly on the granulations of the former ground, which is called *re-biting*. It is done by making the ground much stronger than the one used before. The process for the second ground is the same as for the first; retouching with the acid those tints which require more depth, and stopping out those parts that are sufficiently dark. Another proof must be taken, and the plate then finished with the burnisher, which some use with oil, but others prefer to use dry, previously filling the whole plate with powdered white lead, by which it can be seen how much has been burnished down according to the quantity of colour left in the plate.

AQUEDUCT, or AQUÆDUCT, is usually an elevated channel for the conveyance of water. Aqueducts were most extensively used by the Romans, and in the vicinities of many of their more important cities, in Asia and Africa, as well as in Europe, remains of extensive constructions of the kind yet exist. Rome itself was supplied with water from sources varying from 30 to 60 miles in distance, and at one period of its history no less than twenty aqueducts brought as many different streams of water across the wide plain or Campagna in which the city stands. Great portions of the distance were of course in every case occupied by artificial channels winding along the sides of hills and mountains; and long tunnels carried the streams through these natural barriers when occasion required; but nevertheless the arcaded duct led the streams across the deep valleys, and the aqueduct was in every case required to carry it onwards from the hills over the wide plain into reservoirs in Rome. In one of these Roman aqueducts the series of arches is calculated at nearly 7000, their height being in many places more than a hundred feet. There is nothing more interesting or more really beautiful in the existing ruins of ancient Rome than the remains of these splendid works, three of which, having been restored and repaired, supply the modern city abundantly.

Among the most celebrated modern aqueducts are that of Caserta in the kingdom of Naples, of Maintenon near Versailles in France, and that of Bemfica, called *Agoas Livres*, near Lisbon in Portugal.

The finest aqueduct of modern times, perhaps, is the Croton Aqueduct, which supplies New York with water. It extends 42 miles across a hilly country on the east side of the Hudson river, diversified with ravines, water courses, and public roads. At a place called Sing Sing, the river Croton is dammed up for a distance of five miles, so as to attain at one point a height of forty feet above its original level. The pond of water caused by the dam covers four hundred acres of ground. The water enters the aqueduct from this pond through a tunnel one hundred and fifty feet long; and the gradients are so arranged that the water descends along the aqueduct at the rate of two feet per second. The channel for the conveyance of the water involves very costly engineering. There are fifteen tunnels, varying in length from 150 to 900 feet; the tunnels through rock are left in their natural state, but those in an earthy soil are bricked. The aqueduct is carried across ravines by means of embankments, provided with culverts for streams; and over the larger rivers and the turnpike roads it is carried by well-constructed bridges. One of these bridges consists of a single elliptical arch, considered at the time of its erection to be the largest arch in America; it is 88 feet span, 33 feet versed sine, and 80 feet from the foundation to the crown of the arch. On Manhatten Island there are bridges which cross eight or ten of the public streets, over which the aqueduct is carried. The aqueduct terminates at the part of New York called 144th Street, where there is a receiving reservoir which occupies 30 acres of ground. From this reservoir the water is conveyed to the distributing reservoir on Murray Hill, covering an area of 10 acres: the channel of conveyance from one reservoir to the other being iron pipes. The distributing reservoir is 114 feet above high-water level; and from this point the water is conducted through the city in pipes. The aqueduct crosses the Haarlem river, at a height of 120 feet, by a bridge of fifteen arches, eight of 80 feet span, and seven of 50 feet span. The expense of this great work has been about 12,000,000 dollars; and the power of supply is stated at the enormous quantity of 50,000,000 gallons per day, so that any increase of population can be met by additional draw-pipes from the great reservoir. The reservoir being as high as the cupola of the city hall, the water can be supplied to the summits of nearly all the houses in and near New York.

One of the most remarkable existing aqueducts is the Alleghany wire suspension aqueduct, built at Pittsburg in 1845. It consists of seven spans, of 160 feet each. The trunk or channel of the aqueduct is made of wood, 1140 feet long, 14 feet wide at bottom, 16½ feet at top, and 8½ feet deep; it is formed of double layers of thick plank, united in a very durable manner. The bottom of the trunk rests upon transverse beams arranged in pairs, four feet apart; and between these are the posts which support the sides of the trunk. There are outside posts, which support the side walk and towing path. Each pair of beams is supported on each side of the trunk by a double suspension rod of 1⅛ round iron, bent in the shape of a stirrup, and mounted on a small cast-iron saddle, which rests on the cable. This cable (of which there are two, one on each side of the trunk) is 7 inches in diameter, perfectly solid and compact, and constructed in one piece from shore to shore of the Ohio, 1175 feet long; it is composed of 1900 wires, ⅛ of an inch thick, laid parallel, and subjected to equal tension; each wire was separately coated with a protective varnish, and the whole bundle is encircled by a close, compact, continuous wrapping of annealed wire. The whole cable appears like a solid cylinder; it is stronger and more elastic than an equal weight of iron chain. The cable passes over the tops of short pyramids, built of masonry, and placed in a line between the trunk and the towing path; the pyramids are so small and so simple that they offer no obstruction to the tow-rope passing over them. The extremities of the cables do not extend below ground, but are connected with anchor-chains which are buried beneath



KNIGHTS CYCLOPÆDIA OF THE Industry of all Nations

No. 6.

masses of masonry sunk in the ground. The theory of construction throughout has been to form a wooden trunk strong enough and firm enough to support its own weight, and to combine this with wire cables of sufficient strength to bear the weight of water in the trunk; and a very efficient and economical structure has been thus produced. Each cable weighs 110 tons; the weight of water in the aqueduct is 2100 tons; the deflexion of the cables between the piers is 14½ feet.

AQUILARIACEÆ, is the botanical name for an order of plants, of which there are three species useful in the arts. *A. Malaccensis*, the *Bois d'Aigle*, or Eagle-wood, is a native of Malacca, and produces a whitish yellow wood. This is the *A. ovata* of some botanists. *A. Agallochum* is a native of the East Indies, where it is called *Ugoor* or *Ugooroo*, by the natives, and *Lignum-aloes*, or Aloe-wood, by the Europeans. The wood has a fine scent, and is supposed to be the *Calambac*, or *Agallochum*, of the ancients. *A. secundaria* is another species which also yields a scented wood, and has been known in the Materia Medica, and used in perfumery, under the names of Agallochum, Lignum-aloes, and Aloe-wood. In a healthy state this wood is said to be white and inodorous; but it is subject to the attacks of disease, which causes the secretion of a resinous matter, and the wood then becomes coloured, and gives out a powerful scent. This secretion resembles camphor in many of its properties, and has a bitter flavour: hence the name of the tree.

ARABESQUE. This name is intended to mean simply 'in the Arabian manner,' and is a French form of that expression. The mode of enrichment which it refers to was practised in the decoration of their structures by the Moors, Saracens, or Arabians of Spain. The most celebrated arabesques of modern times are those with which Raphael ornamented the piers and pilasters of the arcaded gallery of the palace of the Vatican which bears his name. The term Arabesque is more applied to painted than to sculptured ornament, though it is not restricted to the former.

ARABIA; *Products and Industry:*—This country is rich in vegetable productions useful in the arts and in domestic economy. It has long been celebrated for the abundance of its odoriferous plants. The frankincense of Saba is alluded to by the prophets Isaiah and Jeremiah. Herodotus mentions frankincense, myrrh, cassia, cinnamon, and laudanum, as productions exclusively peculiar to Arabia; though his information on the products of Arabia is neither extensive nor exact. Among the Romans, also, Arabian odours seem to have been quite proverbial.

The coffee-shrub is cultivated chiefly on the western descent of the chain of hills which, in the province of Yemen, separates the level country from the high-land: that grown at Bulgosa, near Beit-el-Fakih, and exported from Mocha, still maintains its superiority over the coffee produced in the European colonies in all other parts of the globe. The farinaceous deposit called manna, familiar to all readers from the use made of it by the Israelites during their wanderings in the desert, is now, according to Niebuhr, chiefly, if not exclusively, found on the leaves of a species of oak called *ballôt* or *afs*: according to others, it is a pellucid substance exuded by the leaves of different kinds of trees, chiefly the *hedysarum alhagi* of Linnæus. Grapes are cultivated in several parts of Arabia, though in the Koran wine is forbidden to the Mussulmans. In Yemen, where some pains are bestowed upon agriculture, Niebuhr saw excellent wheat, Turkey corn or maize, durra, barley, beans, lentils, tobacco, &c.; senna and the cotton-tree are also cultivated here. Much indigo is grown about Zebid. Niebuhr says that he saw no oats in Arabia: the horses are fed on barley, and the asses on beans. The time of the harvest varies. At Muscat, wheat and barley are sown in December, and reaped in March; in the high-land, near San'á, the time of the harvest for barley is about the middle of July.

Arabia is rich in indigenous trees; the *acacia vera*, from which the gum-arabic is obtained, the date-tree, and many varieties of the palm and fig-tree, deserve to be particularly noticed. Forests appear to be rare. In the barren tracts of the country, the Beduins sometimes supply the deficiency of fuel by the dried dung of the camel.

Among the ancients, Arabia was celebrated for its wealth in precious metals; yet, according to the accounts of modern travellers, Arabia possesses at present no mines either of gold or silver. Iron mines are noticed by Niebuhr as existing in the territory of Saade. The lead mines of 'Omán are, according to him, very productive, and large quantities of lead are exported from Muscat.

The pearl-fisheries of the Persian Gulf are universally celebrated. The bank on which pearl-shells are principally found extends from the Bahreín islands to very near the promontory of Julfar. The northern extremity, near the isles Karek and Bahreín, is distinguished as particularly rich in pearls.

The tents of the Beduins are made of a coarse kind of dark-coloured cloth, woven by their own women. There is but little furniture in a Beduin tent: a mat of straw is used as table, chairs, and bedstead; spare clothes are kept in bags. The kitchen apparatus is very simple and portable. The pots are made of copper lined with tin; the dishes of the same metals, or of wood. Their hearth is easily built; they merely place their caldrons on loose stones, or over a pit dug in the ground. They have neither spoons, knives, nor forks. A round piece of leather serves them as table-cloth, in which the remains of the meal are preserved. Their butter, which the heat soon melts down, they keep in leather bottles. Water is kept in goats' skins; a copper cup, carefully tinned over, serves as a drinking vessel. Wind-mills and water-mills are unknown: all grain being ground in a small hand-mill. There are no ovens in the desert: the dough is either kneaded into a flat cake, and baked on a round iron plate, or it is formed into large lumps, which are laid between glowing coals till they are sufficiently baked.

ARABLE LAND, is that part of the land which is chiefly cultivated by means of the plough.

Land in general is divided into *arable land*, *grass land*, *wood land*, *common pasture*, and *waste*.

The German agriculturist Thaer has given a classification of arable soils of known qualities, worthy of notice. It is as follows:—

No.		Clay, p. cent.	Sand, p. cent.	Carb. of Lime, p. cent.	Humus, p cent.	Value.
1	First class of strong wheat soils . . .	74	10	4½	11½	100
2		81	6	4	8⅘	98
3		79	10	4	6½	96
4		40	20	36	4	90
5	Rich light sand in natural grass.	14	49	10	27	?
6	Rich barley land . .	20	67	3	10	78
7	Good wheat land . . .	58	36	2	4	77
8	Wheat land .	56	30	12	2	75
9	Ditto . . .	60	38	Very insignificant quantities.	2	70
10	Ditto . . .	48	50		2	65
11	Ditto . . .	68	30		2	60
12	Good barley land . . .	38	60		2	60
13	Ditto, second quality . .	33	65		2	50
14	Ditto . . .	28	70		2	40
15	Oat land . .	23½	75		1½	30
16	Ditto . . .	18½	80		1½	20

Below this are very poor rye lands.

In all these soils the depth is supposed the same, and the quality uniform to the depth of at least six inches; the subsoil sound, and neither too wet nor too dry. The last column, of comparative value, is the result of several years' careful valuation of the returns, after labour and seed had been deducted.

Under the article SOIL the comparative qualities of different kinds of agricultural land are noticed. We may in this place briefly illustrate the nature and qualities of arable land by tracing the history of a corn crop.

The better the soil, the less cultivation it requires to produce tolerable crops; hence, where the land is very rich, we find in general a slovenly culture; where the ground is less productive, more labour and skill are applied to compensate for the want of natural fertility. The simplest cultivation is that of the spade, the hoe, and the rake—and on a small scale it is the best; but spade husbandry cannot be carried to a great extent without employing more hands than can be spared from other occupations. The plough, drawn by oxen or horses, is the chief instrument of tillage, and has been so in all ages and nations of which we have any records. Its general form, and the mode of using, are explained under PLOUGH. The main object of ploughing is to turn over the whole surface of the ground, as a preparation for bringing it to a finely pulverized state, and to admit the atmosphere to act upon parts before excluded from it. When grass-land or stubble is ploughed, care must be taken to bury the grass and weeds completely, and the slice cut off by the plough must be turned over entirely, which is best done by making the width of the furrow greater than the depth. When the grass and weeds are rotten, and the ground is ploughed to pulverize it, a narrow deep furrow is best; the earth ploughed up is laid against the side of the preceding ridge, which forms a small furrow between the tops of the ridges, well adapted for the seed to lodge in and to be readily covered with the harrows. The Norfolk farmers are very careful not to break the *pan*, as they call it, in their light lands: this *pan* is formed by the pressure of the sole of the plough and the tread of the horses, and opposes a useful bank to the too rapid filtration of the water; it lies from five to eight inches below the surface. If it is broken, the manure is washed down into the light subsoil, and the crop suffers, especially when sheep have been folded, their dung being very soluble. In such soils an artificial pan may be formed by the *land-presser*, or *press-drill*. [PRESS DRILL.]

The mode in which the soil is prepared most perfectly for the reception of the seed is best shown by following the usual operations on fallows. After the harvest, the plough is set to work, and the stubble ploughed in. The winter's frost and snow mellow it, while the stubble and weeds rot below. In spring, as soon as the weather permits, it is ploughed again, the first ridges being turned over as they were before: this completes the decomposition of the roots and weeds. It is then stirred with harrows, or other instruments, which tear up the roots that remained; and some of these, not being easily destroyed, are carefully gathered and burnt, or put in a heap to ferment and rot, a portion of quick lime being added. Another ploughing and stirring follows, at some interval, till the whole ground is mellow, pulverized, and free from weeds; manure is put on, if required, and immediately spread and ploughed in; the land is then prepared for the seed.

Various instruments have been invented to stir the earth and mix it, subsidiary to the ploughing, and also to loosen and separate roots and weeds. These are described under HARROW; they all consist of series of spikes or teeth, which are made to break up the clods of earth. When the soil turned up by the plough is in large hard lumps, a roller, sometimes with spikes in it, is drawn over the land to break the clods, or mallets are used to break them by hand; but this is seldom necessary except where very stiff soils have been ploughed when too wet, and the ridges have dried and been ploughed again in dry weather.

When the land has been duly prepared, the seed is sown. This is done sometimes before the last ploughing, but then the manure should have been ploughed in before; for, except in planting potatoes, which are not a seed but a bulb, the manure should always be deeper, and not in contact with the seed. When the seed is ploughed in, the furrow should not be above two or three inches deep, and eight or nine wide; and it is only in particular soils that this mode is to be recommended. The most common method is to sow the seed on the land after the last ploughing, and draw the harrows over to cover it: when the land has been well ploughed, and especially if the press-drill has followed the plough, the seed will mostly fall in the small furrows made by two adjoining ridges, and rise in regular rows. The various modes of sowing are described under DRILL and SOWING.

The proper season for sowing each kind of grain, the choice of seed, and other particulars, are explained under the name of the different seeds usually sown. As a general rule, it may be observed, that the smaller the seed, the less it must be covered, and clover or grass seed are not usually harrowed in, but only pressed in with the roller.

It has been found by experience, that besides the general exhaustion of *humus* (decaying vegetable matter) produced by vegetation, especially by those plants which bear oily or farinaceous seeds, each kind of crop has a specific effect on the soil, so that no care, or manure, can make the same ground produce equal crops, of the same kind of grain, for any length of time without the intervention of other crops. The various important circumstances which bear on this question are noticed under FALLOW, FARM, and ROTATION OF CROPS.

The quantity of arable land in Great Britain was roughly estimated some years ago as follows:—England, 10,900,000 acres; Scotland, 2,500,000 acres; Wales, 900,000 acres. It was ascertained in 1847 that in Ireland, in that year, about one-fourth of the whole area (= 5,238,575 acres out of 20,808,271) was under crops, one sixth under corn culture, ond one eighteenth under pasture and clover.

A'RACHIS, is the botanical name of a kind of pulse, called the Earth-Nut, which is much cultivated in the warmer parts of the world: it belongs to the pea tribe, to which and the bean it is botanically related. The seeds are considered a valuable article of food in Africa, and the tropical parts of Asia and America. In flavour they are as sweet as an almond; and they yield, when pressed, an oil in no respect inferior to that of olives. The plant will only grow in a light sandy soil, in which its pods can readily be buried, and it requires a climate as hot at least as that of the south of France.

ARACK, or ARRAC, a distilled spirit prepared from different substances, more especially from sweet juice (toddy) extracted from the unexpanded flowers of different species of the palm tribe. In Ceylon, where a large quantity of arack is manufactured, it is entirely distilled from cocoa-nut tree toddy. The 'toddy topes,' or cocoa-nut tree orchards, are very extensive in Ceylon, and their produce is collected for the distillation of arack, and the manufacture of sugar and oil.

In Ceylon, when it is intended to draw toddy from a tope, the toddy-drawer selects a tree of easy ascent, and connects the upper branches of other trees to it, so as to pass readily from one to another. He ties the flowering spath in different places, and bruises it with the blow of a small mallet; this is done twice a day for a week; after which a portion of the spath is cut off, and juice slowly exudes from it. Successive portions of each spath, and successive trees in the tope, are treated in the same way. The juice or toddy is collected in gourds, from which it is emptied into vessels.

Arack may be distilled from toddy the same day it is drawn from the tree, but sometimes this operation is delayed until it becomes sour.

The process of distillation is carried on in the maritime provinces in copper stills, but in the interior of the island earthen vessels are chiefly employed. Toddy yields by distillation about one-eighth part of proof-spirit.

On the peninsula of India, arack is distilled from the flowers of two or three different trees. In Java it is made from molasses, palm-wine, and rice. In Turkey it is made from the skins of grapes, flavoured with aniseed; the mountain Tartars distil it from many berries and fruits; and the Calmucks from milk.

Ceylon exports annually, and for the most part to the presidencies of Bengal, Madras, and Bombay, from 5000 to 6000 leaguers of arack, each containing 150 gallons. The prime cost of arack at Colombo in Ceylon varies from 8*d.* to 10*d.* per gallon. Ceylon arack is superior to Batavian arack, and it commonly brings a higher price of from 10 to 15 per cent. on the peninsula of India than Javanese manufactured spirits.

It is said that factitious arack is sometimes sold, made by dissolving flowers of benzoin in pale Jamaica rum. The name of *Vauxhall Nectar* has been given to this mock arack.

ARÆO'METER, is an instrument employed for the purpose of ascertaining the specific gravities of light substances, fluid or solid. Nicholson's aræometer consists of a hollow copper vessel, from each extremity of which proceeds a stem; that which, when the instrument is in a vertical position, is uppermost, is a wire of hardened steel about $\frac{1}{40}$ inch in diameter, carrying at its top a small cup in which weights may be placed: to the lower stem, which is short, is attached a stirrup carrying a cup in which may be placed a solid body whose specific gravity it may be required to determine. The instrument is so adjusted that if a weight equal to 1000 grains be placed in the upper vessel, the whole will sink in distilled water at a temperature expressed by 60 degrees of Fahrenheit's thermometer, till a mark made on the stem is on a level with the fluid surface. When the specific gravity of a fluid, whether lighter or heavier than water, is to be determined, the instrument is plunged into the fluid, and weights are placed in the upper vessel till the mark on the stem is at the surface.

To obtain the specific gravity of a solid which does not imbibe water; the instrument is placed in distilled water, the body is laid in the upper vessel, and weights are added till the mark on the stem is at the level of the surface; these weights being subtracted from 1000 grains, leave the weight of the body in air: then, placing the body in the lower vessel, let other weights be added in the upper one till the mark on the stem is again at the surface of the water; these additional weights will express the loss which the body sustains by being immersed in water.

If the substance whose specific gravity is required be, like wood, capable of imbibing water during the experiment, it should be left in the lower vessel, while under water, till the instrument is stationary, when the additional weights in the upper vessel will express the weight of the displaced water together with that which is imbibed; then, having dried the surface, let the substance be placed in the upper vessel and weighed in air as at first: the difference between this weight and that which was found before the substance was put in the water is the weight of the water imbibed; and this must of course be subtracted from the observed weight of the substance in water, previously to substituting the values of the terms in the last proportion.

The instrument more usually employed to determine specific gravities is the HYDROMETER.

A'RAGON; *Produce and Industry*:—This province of Spain produces wheat, barley, rye, oats, Indian corn, leguminous vegetables, esparto or Spanish broom, flax, hemp, sumach, barilla madder, saffron, liquorice, fruits, oil, wine, and timber. The productions of the mineral kingdom are gold, silver, copper, iron, lead, quicksilver, cobalt, alum, jet, coals, and copperas; few of these mines are now worked. Peat earth is found in the district of Teruel, and is used for fuel. The mountains abound in game. Before the Peninsular war the number of sheep was 2,050,000 heads. The produce of grain and wine is more than sufficient for the consumption: but there is a deficiency of horned cattle and mules, which are supplied from France. The industry of Aragon is very limited and consists principally in manufactories of common cloth, hemp sandals, sacks, and cordage, hats, leather, paper, earthenware, and some iron foundries.

ARAUCA'RIA, is the name of a singular genus of gigantic firs, of which the *Norfolk Island pine* is the best known. This tree is found not only in the spot after which it has been named, but also in several other places in the South Seas, as in New Caledonia, Botany Island, Isle of Pines, and in some parts of the east coast of New Holland. It is described as a most majestic tree, growing to the height of from 160 to 228 feet, with a circumference sometimes of more than 30 feet. Its trunk rises erect, and is sparingly covered with long, drooping, naked branches. The bark abounds in turpentine; the wood, which is destitute of that substance, is white, tough, and close-grained. It was once expected that this tree would have been valuable for its timber, and that it would have afforded spars for the navy of great size; but it has been found on trial to be too heavy, and so unsound, that Captain Hunter could only find seven trees fit for use out of thirty-four that he caused to be felled. Its wood is, however, useful for carpenters' in-door work. Several specimens of this tree exist in the collections of this country. Unfortunately it will not live in the open air in the winter, and its growth is so rapid as to render it very soon too large for the loftiest greenhouses.

ARBALEST or ARBLAST, a cross-bow, appears to have been derived from the larger *ballistæ*, and was probably introduced into England by the Normans, who used it with great effect at the battle of Hastings. The arrows used for the cross-bow were called *quarrels*, from the French *carreaux*, a term which indicates the square form of their heads.

ARBORETUM. An Arboretum in its botanic sense, is a plantation of trees; in its *social* sense, it has become associated with an improvement which marks the present age—the planning and laying out of parks for the people: pleasure grounds where the artizan can breathe the fresh air at intervals. The Derby Arboretum is an example of the munificence of a distinguished family of manufacturers, the Messrs. Strutt. Mr. Joseph Strutt presented to the corporation of Derby, in 1840, a people's park or arboretum, on which he had expended about 12,000*l*. It was beautifully laid out by the late Mr. Loudon, and so supplied with trees, shrubs, and flowers, ticketed and labelled, as to be a kind of botanic garden as well as a pleasure-ground. It was given to the inhabitants, with the corporation as trustees. We must express a regret, however, that a *charge* is made for admission, to defray the expense of keeping up the ground: this should not be—after so munificent a gift, the least that the town could do would be to appropriate a small annual sum for maintenance.

ARBOR VITÆ is the familiar name given to a tree, the botanical name of which is *Thuja* or *Thuya*. There are many species. The American Arbor Vitæ is a large shrub or small tree, sometimes called *white cedar;* the wood is very durable, but is difficult to obtain except in small pieces; it makes excellent posts and rails, and the branches are used for making brooms. The Chinese and the Weeping Arbor Vitæ are not much employed in the arts. The Callitris Arbor Vitæ is said by Broquiart and other authorities to yield the useful substance Gum Sandarac [SANDARAC]; and the wood of this tree, under the name of *alerce*, is in great repute in the east for building religious edifices; the roof of the celebrated cathedral of Cordova is built of this wood, and exemplifies the fitness of the material for such purposes.

ARC, a bow, signifies any part of a curve line. The straight line which joins the extremities of the arc is called its chord.

The practical method of finding the length of an arc is as follows:—Divide the arc into a number of smaller arcs, making the number large in proportion to the degree of accuracy required, and add together the chords of the smaller arcs. The sum of the chords will differ very little from the arc, even when the number of sub-divisions is not very large. For instance, the arc of the quadrant of a circle, whose diameter is ten million of inches, is 7,853,982 inches, within half an inch. Divide this quadrant into ten equal parts, and the sum of the chords is 7,845,910 inches: divide the quadrant into fifty parts, and the same sum is 7,853,659 inches, which is not wrong by more than one part out of 24,316. For only twenty sub-divisions the sum of the chords is 7,851,963 inches, wrong only by one part out of 3890. Therefore, for every practical purpose, an arc of a circle (and the same may be said of every other curve) is the polygon made by the chords of a moderate number of sub-divisions of the arc.

ARCADE properly signifies a series of arches on insulated piers, forming a screen, and also the space inclosed by such.

In addition to its proper technical meaning, this term has of late acquired a different signification among us as the popular name for what the Parisians more properly designate a 'passage' or 'galerie,' viz. an alley lined on each side with shops, and roofed over so as to be in fact a sort of in-door street, entirely protected from the weather, and of uniform design throughout in its architecture. As to such a place being a very great public convenience there can be but one opinion,—as in dirty or wet weather, when the advantages attending such mode of building make themselves felt very sensibly. The Burlington Arcade was the first place of the kind in London. Among the Parisian arcades the Passage Colbert is one of the most striking, both for its extent and architectural display, towards which last its Rotunda contributes in no small degree.

ARCH is the general name for any solid work, whether of masonry or otherwise, of which the lower part is formed into an arc of a curve supported at the two extremities.

The lower supports are the *piers* of the arch; the arch is said to *spring* from the tops of those piers; the summit of the arch is the *crown*, and on either side of the crown are the *flanks* of the arch. The lower line of the arch stones is called the *intrados* or *soffit*, the upper, the *extrados* or *back;* the arch stones are called *voussoirs*, and the highest voussoir the *key-stone.* The width from pier to pier is the *span;* and the vertical distance from the crown to the level of the top of the piers is the *height.* The voussoirs are cemented together; and if the cement were sufficiently strong, any form might be given to the arch, or at least any form which would stand if cut out of the solid material. If we suppose the stones uncemented, their friction upon one another would tend to prevent the disturbance of equilibrium, and allow considerable variety of form in arches constructed with stones of the same weight. But if we suppose the stones perfectly smooth, so that each of them is kept from slipping only by the pressure of the adjoining two, then each intrados has one particular form of extrados and one only, so long as the manner in which the stones are cut follows one given law.

The applications of the arch, in practice, are noticed under ABUTMENT; BRIDGE; BUTTRESS; IMPOST; PIER, &c.

Sir M. I. Brunel introduced, a few years ago, a singular mode of constructing arches. In the construction of stone arches, some kind of centering is necessary, to support the single stones until by mutual pressure they can support each other; but Brunel devised the following mode in respect to brick arches. The piers of the bridge or arch having been constructed in the usual manner up to the springing, he commenced building a portion of the arch right and left, on both sides, taking care that both arches progressed at an equal rate, so that they might balance each other. In order to increase the cohesion of the structure, he introduced bands of hoop iron longitudinally between the courses; and by these means he was enabled to carry on the two semi-arches, until they met those produced in a similar way from the opposite piers. A narrow arch, say about four feet in width, having been thus completed, Brunel proposed to extend it to the requisite width by building on each side of it, adding from nine to eighteen inches at a time. To shew that—whatever might be the difficulties in practice—the principle is sound, Sir M. I. Brunel constructed two semi-arches, of bricks laid with mortar prepared with blue lias lime. Several bands of hoop iron, and several slender rods of fir, were inserted longitudinally between the courses, extending throughout the whole length of the structure. The radius of curvature of the arch was 177 feet, and although only 4½ feet wide at the top, it was extended to the length of 40 feet on each side of the centre pier. One end was afterwards extended an additional 20 feet; and as the other end could not be extended in the same way, in consequence of want of space, a weight of 28½ tons was suspended from it as a counterpoise. Although the structure fell about three years after its completion, the fall was owing to circumstances independent of the principle on which the arch was constructed.

The origin of the arch in actual constructions is still unknown; it cannot be stated with any degree of certainty, either in what country or at what epoch it was first used. There is reason to think that it was unknown to the Greeks at the time when they produced their most beautiful temples, in the fifth, fourth, and third centuries before the Christian æra. The want of the arch would lead them to contract the intercolumniations, or spaces between the columns, and to the general and frequent adoption of columns as the only mode of supporting a superstructure.

It is maintained that there are brick arches at Thebes in Egypt, which belong to a very remote epoch, and one long prior to the occupation of that country by Alexander the Great. Etruria seems to have been the first European country in which the arch was used. The great sewer of Rome, commonly called the Cloàca Maxima, is an arched construction, which probably belongs to the age of the Tarquins.

The application of the arched structure is one of the most useful mechanical contrivances. By means of it small masses of burnt clay, and conveniently sized pieces of soft and friable sandstone, are made more extensively useful for the economic purposes of building, than the most costly and promising materials were in the hands of the Greeks and Egyptians. By means of it cellars are vaulted; subways, or sewers, are made to pass under heavy structures and along streets with certainty and safety; and secure and permanent roadways for every purpose of communication are formed across wide, deep, and rapid rivers.

The Romans did not deviate much from the semicircular form. Arches of smaller segments were certainly used by them, as well as elliptical arches, but in these cases they were fortified with enormous abutments, which proves that the architects knew very well the weak points of such a construction. The architects of the twelfth, thirteenth, and fourteenth centuries, showed what could be done by varying the form and construction of the arch.

The pointed arch, upon its invention or first introduction into Europe, seems to have exercised the ingenuity of architects in varying its form and application. This we observe in the numerous ecclesiastical structures in this country, in our beautiful pointed styles, and most particularly in some of the greater churches and cathedrals.

The origin of the pointed arch has been almost as much disputed as the discovery of the principle of the arch itself. It became general in most parts of Europe at nearly the same time, and about the period of the return of the warrior-priests and pilgrim-soldiers of the first crusade. This, and other circumstances which might be adduced, added to the fact of the pointed arch being used in Asia before that period, and that an arch of the pointed form cannot be satisfactorily shown to have been used in the northern and western parts of Europe anterior to it, give a reasonable degree of certainty to the supposition that the notion was brought from the east by the crusaders.

The most notable of the departures from the principle of the arch in building are described under Britannia Bridge; Suspension Bridge.

ARCH, TRIUMPHAL, a structure which the Romans used to erect across their roads or bridges, or at the entrance of their cities, in honour of victorious generals or emperors. They were of two kinds. Temporary arches were made of wood, on the occasion of a triumph. The others were permanent structures, built first of brick, afterwards of hewn stone, and lastly made of, or at least cased with, marble. Their general form is that of a parallelopipedon, which has an opening in the longer side, and sometimes a smaller opening on each side of the large one. These openings are arched over with semicircular arches, and the fronts are decorated with columns and their accessories on lofty pedestals: the whole is surmounted by a heavy attic, on the faces of which inscriptions were generally placed.

Triumphal arches were erected under the republic. Under the emperors these monuments became very numerous, and were overcharged with ornaments. One erected to Augustus at Rimini has the widest opening of the ancient arches, the gateway being 31 feet. Of the triumphal arches remaining at Rome, that of Titus is the oldest. This arch is ornamented with sculptures representing the triumph of Titus, and the ornaments of the temple of Jerusalem which he brought as spoils to Rome. But arches were also raised in honour of emperors for benefits conferred on their country on some particular occasions; such is the fine arch of Trajan on the old mole of Ancona. Another fine arch in memory of Trajan exists at Benevento; it is ornamented with fine rilievi, and is in very good preservation. All these are single arches; but others have two smaller archways, one on each side of the great central one. These are consequently oblong in their shape, and have a heavier appearance than the single arch. Two of these triple arches still exist at Rome, that of Septimius Severus, and that called the arch of Constantine.

There are other arches in various parts of Italy, at Aquino, Aosta, and Pola in Istria, and several in the south of France, of which those of Nismes and Orange are the best preserved. There are several arches in Syria and in Barbary, particularly one at Tripoli, and another at Constantina. In modern times triumphal arches have been raised in imitation of the Roman arches. Those of the gate of St. Denis and the gate of St. Martin, at Paris, were raised in honour of Louis XIV. Bonaparte also had one constructed on the place du Carousel, after the model of the triumphal arch of Septimius Severus at Rome. The much larger arch, the 'Arc de l'Etoile,' at the Barrière de Neuilly, was commenced in 1806, after the battle of Austerlitz, and has only recently been finished (1847.) Another arch (L'Arco della Pace) which was begun by Bonaparte's order at Milan, on the opening of the famous road across the Simplon, has since been completed by the Austrian government. In London there is a single arch at Hyde Park Corner.

ARCHANGEL, considered as a province, has very little to do with the industry of all nations. Its climate is severe, and its productions few. The bread in use is a compound of meal, moss, scrapings of the bark of the pine, and grated roots; yet this food, coarse as it is, is unknown to more northern palates, which must be content with dried fish. The southern districts grow hemp and flax, and a few kinds of vegetables. The forests produce very fine timber. Salt and bog-iron form the chief mineral wealth.

The manufacturing and mechanical industry of the people is principally confined to shipbuilding, the preparation of pitch and tar, and the weaving of linen, which latter occupation fills up the leisure hours of the peasant's wife in the circles of Kholmogory and Archangel, and constitutes a lucrative branch of their commerce with St. Petersburg, Moscow, and other Russian marts. Pitch, tar, timber, tallow, train-oil, hemp, flax, mats, canvas, skins, and furs, are the chief exported produce.

But the *town* of Archangel (the chief place in the province), is notable in a commercial point of view. It is the most northern emporium of trade, and the oldest port, in the Russian dominions. It is now the chief mart of the Russian northern trade, as it was formerly of all the traffic between Muscovy and foreign parts. The exports consist of linseed, rye, oats, wheat, barley, flax, tow, tallow, train-oil, mats, deals, battens and ends, pitch, and tar. The imports, which are generally confined to the town and neighbourhood, are sugar, coffee, spices, salt, woollens, hardware, &c. In 1846 there were 634 vessels cleared, of which 368 were British, the cargoes being valued at 1,063,700*l*. The port is connected by canals with the Volga and the Neva. The navigation is open generally from May to the end of September, and during this period the river is covered with vessels and boats of all sizes; the quays and shores are peopled with multitudes, variously and actively employed; and the great road from Siberia is covered with travellers and loaded carts and waggons. An association called the 'White Sea Company,' was formed at Archangel in 1803; it despatches a fleet of vessels every year on fishery expeditions to the coast of Nova Zembla, Kalguiew, and Spitzbergen, at the last of which the crews sometimes winter.

ARCHERY. A few notices of the mechanical construction of the implements of archery will be found under their proper headings.

ARCHIL, *orchil*, *litmus*, or *tournsole*, is a blue dye procured from the *rocella tinctoria* and *ceanora tartarea*, which are lichens growing abundantly in the Canary and Cape Verde Islands. The colouring matter of these plants appears to be a peculiar vegetable principle which has been called *erythrine*: it may be extracted either by means of alcohol or ammonia, but the latter is employed by those who manufacture the colour, which is generally sold in small flat pieces, and known by the name of litmus.

Archil is brought to market in three states —violet-red liquid paste, blue lumps, and powder. It is employed by chemists to ascertain the presence of acids in solution, because it has the property of changing from blue to red by contact with acids; and it also detects alkalies, by restoring the blue which had been changed by acids. Archil is never used alone as a dye, on account of its want of permanence. It is, however, employed for the purpose of deepening and improving the tints of other dyes, and it imparts a bloom which it is difficult to obtain from other substances. Liquid archil is much used for staining wood, and tinting silk stockings.

M. Clenchard, a French chemist, has recently (1850) patented a mode of using archil in the dyeing and printing of woollen and silk goods; in which the archil is combined with alkalies and lime, and applied to the woven material with a more direct action than in the ordinary mode of its use.

Archil communicates a beautiful violet colour to marble.

The island of Teneriffe is said to yield annually about 30,000 lbs. of the lichen from which archil is prepared.

ARCHIMEDEAN SCREW. The great Greek philosopher, Archimedes, is associated with many valuable discoveries in science, among which the principle of specific gravity, and certain geometrical theorems, stand out prominently. But the hydrostatic *screw* is the contrivance which connects his name more particularly with the arts. Whether it is true that he travelled into Egypt, and invented the screw as a means of raising the water of the Nile to points which it could not otherwise reach, is a disputed question; but it is known that he was aware of the action of such a screw.

In what way the Archimedean screw may be made available for raising water, is explained under Hydraulics; while its application to steam navigation is noticed under Screw Propeller.

ARCHIPELAGO. The small but luxuriant islands which speckle the Mediterranean, between Greece and Asia Minor, are rich in produce which forms no inconsiderable part of the commerce of Europe and the Levant. Many of these islands are composed almost entirely of a pure white marble, of which the Parian, from Paros, where it was formerly most worked, is often mentioned by ancient writers. The productions of the islands are wine, oil, gum-mastic, raisins, figs, silk, honey, wax, olives, and various fruits, especially the lemon and orange: cotton is grown in small quantities on Milo and other islands, and might be cultivated to a great extent; it is remarkable for its brilliant white hue. Some of the larger islands contain sulphur, alum, iron, and other minerals. An extensive sponge fishery has also long been established among the Sporades, which are noted for their fine sponges.

ARCHITECTURE. A formal treatise on architecture being beyond the limits of the present work, the reader is referred simply to the names of the chief component parts of an architectural structure, and to some of the most famous buildings.

ARCHITRAVE, is the lower part of any structure supported by pillars, or the lower beam which rests upon the columns and joins them together, on which the whole entablature (or ornamental part which comes immediately above the columns) rests. When pillars support an arch, the voussoirs supply the place of an architrave, by which name they are sometimes called. In the same way the flat-beam, or row of stones coming immediately above a door or window, is called the architrave.

ARCHIVOLT, or ARCHIVAULT, is the ornamented band or moulding which runs round the lower part of all the voussoirs of an arch.

ARCH-LUTE, a large lute, or double-stringed theorbo, formerly used by the Italians for the base parts, and for accompanying the voice. This instrument had fourteen notes, the highest whereof was A, the fifth line in the base, the lowest the double G below. It possessed considerable power. It was about five feet in extreme length, and proportionally large in the body. At the commencement of the last century this instrument was much in use. Handel employed it in many of his early operas.

ARCOGRAPH. [Cyclograph.]

ARCTIC FOX, a small species of fox (*Canis lagopus*), celebrated for the beauty and fineness of its fur, which has long been considered a valuable article of commerce. The colour of the fur, as is the case with all animals which inhabit very high latitudes, varies according to the season, being slaty blue in summer, and pure white in winter. It is in the latter state that the fur is most esteemed, not only on account of its colour, but likewise because it is of a closer and finer quality than at any other time, and therefore fitted for producing more costly articles.

ARDECHE, one of the southern departments of France, has considerable manufacturing industry. There are numerous tanneries for shoe and glove leather, paper-mills, cotton, woollen cloth and silk factories. Great attention is paid to the rearing of silkworms, for the production of raw silk, of which about 700,000 lbs. are brought to market annually. The department contains mines of lead, copper, iron, manganese, antimony, alum, and coal: marble of different colours, gun flints, porcelain clay, and pumice-stone abound. Particles of gold are found in the Rhone, the Ardèche, the Erieux, and also mixed with antimony in the mines of the commune of Malbosc.

The number of manufacturing towns is considerable. Annonay, the largest town in the department, has numerous establishments for dressing kid and lamb skins for glove leather, the annual value of which amounts to 6,000,000 francs; there are also several silk-mills, and paper factories which produce the best paper in France; the value of the paper made here is stated to be 3,000,000 francs a year; the production of white silk for the manufacture of blondes and tulles has rapidly increased of late years.

ARDENNES, a department of France on the Belgian frontier, has manufactures in ironmongery of all kinds, broad cloth, cashmere shawls and other woollen stuffs, shoe and white leather, hosiery, coarse linen, and hats; there are also several glass-works, iron-furnaces, and brass-foundries. Coal, iron, slate, porcelain clay, and sand used in the manufacture of plate-glass, are found. At Charleville the chief manufactures are fire-arms, hard-ware, and nails; there are also soaperies and brass-foundries in the town. Rethel is a busy place, and is largely engaged in the woollen manufactures; it contains also several tanneries, breweries, and iron-foundries. The environs are fertile, yielding good pasturage and timber, and contain stone quarries and iron-mines. Sedan has been long famous for its fine broad cloths, and especially for its fine blacks. The total yearly value of this manufacture is set down at 16,000,000 francs. The environs are studded with factories and workshops, engaged in the woollen trade; there are also several iron-works, tanyards and dyehouses.

ARDROSSAN is worthy of our attention, for the part which it now fills in the system of steam navigation. Placed on the west coast of Scotland, near Ayr, it has railway communication with Glasgow on the north-east, and with Carlisle on the south-east. The port having many natural advantages, a harbour was commenced there in 1806; it has been for many years in a state to receive shipping, and is now considered one of the safest and most accessible on the west coast of Scotland. Steamers ply regularly from Ardrossan to various ports of England, Scotland, and Ireland.

ARDWICK LIMESTONE, is a calcareous bed or series of beds containing shells and fish remains, in the upper part of the coal formations of Manchester and Lebetwood. There is a coal-bed above it at Manchester.

ARE, is the modern French measure of surface, forming part of the decimal system adopted in that country after the revolution. It is obtained as follows:—the metre or measure of length, being the forty-millionth part of the whole meridian, as determined by a trigonometrical survey, is 3·2809167 English feet; and the *are* is a square, the side of which is 10 metres long. The hectare is generally used in describing a quantity of land. It is 2·4711695 English acres, or 404⅔ hectares make 1000 acres.

A'REA, is the *superficies* or *quantity of surface* in a plane figure. The measuring unit of every area is the square described upon the measuring unit of length: thus, we talk of the square inches, square feet, square yards, or square miles, which an area contains.

Any figure which is entirely bounded by straight lines may be divided into triangles; and the area of each triangle separately determined. This determination may be made in either of two ways. 1st. Measure a side of the triangle, and the perpendicular which is let fall upon it from the opposite vertex, both in *units;* half the product of these two lengths is the number of square *units* in the triangle. 2nd. Measure the three sides in *units;* take the half sum of the three, from it subtract each of the sides, multiply the four results together, and extract the square root of the product; this gives the number of square *units* in the triangle.

To find the area of a *parallelogram*, multiply one side by its perpendicular distance from the opposite side; for a *rectangle*, multiply two adjacent sides.

To find the area of a *circle*, multiply the radius by itself and the result by 355; then divide by 113. In all these cases, the result is in the *square* units corresponding to the *linear* units in which the measurements were made.

The above are a few practical rules, useful for every day purposes.

ARECA. [Betel Nut.]

ARENG. [Palms; Sago.]

AREQUIPA, one of the largest and finest cities of Peru, has considerable industry and commerce. Gold and silver cloths, woollens, and cottons, are manufactured at Arequipa, which carries on a great trade with Buenos Ayres, exporting brandies, wine, flour, cotton, and sugar; and importing cattle, dried flesh, tallow, cocoa, &c. The great commercial road from Lima to the southern provinces passes through the city.

ARFE, is the name of two very distinguished Spanish silversmiths, and the designers and constructors of several of the most costly tabernacles which do or did adorn the cathedrals of Spain.

Henrique de Arfe, the elder, and the grandfather of the other, Juan de Arfe, made, between 1506 and 1524, the silver tabernacles of the cathedrals of Leon, Cordova, and Toledo. He also made the tabernacle of the Benedictine monastery of Sahagun, besides a great many crucifixes and other articles used in Roman worship.

Juan de Arfe y Villafane, the grandson, was born at Leon in 1535. He is the artist of three of the finest tabernacles in Spain—those of Avila, Seville, and Osmas. He made also tabernacles for the cathedrals of Burgos and Valladolid, and one for the church of St. Martin at Madrid. Arfe was much employed by Philip II. and Philip III.; the former appointed him assayer of the mint of Segovia. He was both engraver and writer.

ARGAND LAMP, a kind of lamp in which the wick, and consequently the flame also, is in the form of a hollow cylinder, through the interior of which a current of air is made to ascend, in order to afford a free supply of oxygen to the interior as well as to the exterior of the flame; and thereby to ensure more perfect combustion and greater brilliancy of light than could be obtained either by the use of a single large wick, or by a series of small wicks arranged in a straight line. These objects are more perfectly attained by the addition of a glass chimney, which confines the air immediately surrounding the flame, and produces an upward current which causes it to rise high above the wick. This arrangement was invented about 1782, by Aimé Argand, a native of Geneva. It is made in many different forms, one of which, with a chimney of copper instead of glass, is used in chemical operations for the emission of heat. The principle is also extensively applied to gas-burners.

Mr. Hemmenway took out an American patent in 1841, for a means of avoiding the necessity of removing the oil chamber when an argand lamp is to be replenished with oil. The fountain or reservoir is to be supplied with oil through a short pipe at top, which is hermetically closed by a leather valve and screw cap; and between the bottom of this reservoir and the pipe that conducts the oil to the burner, is an air chamber, which is supplied with air by a tube passing up through the oil reservoir. This air is made one of the means of filling the vessel with oil.

Messrs. Bedington and Docker registered an improvement in 1849, whereby an argand lamp is enabled to maintain a clear light for a greater number of hours than under ordinary circumstances. The central air-tube, instead of terminating, as in the usual argand lamps, nearly on a level with the top edge of the perforated air-cone, is carried about half an inch higher, and has apertures made near its upper end. The outer case is also prolonged at top to a similar extent, and is similarly perforated near the top. By this arrangement, currents of air are directed through the apertures into the wick, just below the point of inflammation; and thus the oil is prevented from becoming thickened or carbonized at that spot, which is so likely to occur in the ordinary form of argand.

Many other improvements have from time to time been introduced in the argand lamp; and our manufacturers in London and Birmingham, in the various Exhibitions of Manufactures which have taken place within the last few years, have shown how much external beauty as well as practical convenience may be imparted to these contrivances.

The name of Argand having become associated with the means of producing a bright light by a judicious arrangement of air-holes, it has been applied not only to lamps, but also to candles and furnaces. During more than forty years, attention has from time to time been directed to the possibility of producing Argand Candles—that is, candles constructed on the argand principle. As, in the argand lamp, air is supplied *within* the circle of the flame, so it has been thought that if air could ascend through the wick of a candle, the flame produced would be more brilliant. Many varieties have been tried, and some of them patented; but none of them have yet become permanently and commercially successful.

The designation Argand Furnace has been lately given to an arrangement, in which a stream of air is made to mingle with the inflammable gases in the furnace, but is previously divided into a number of minute streamlets by passing through small apertures. The principle has been known and partially acted on for a considerable time, but it was brought into a practical form a few years ago by Mr. Williams.

ARGIL. [ALUMINA.]

ARGOL is an acidulous concrete salt which is deposited by wine, and forms a crust on the sides of vessels in which that liquid is kept. This crust becomes hard, brilliant, and brittle; it is easily reduced to powder. The argol brought from Germany, and produced from white wine, is the best. This substance is used by dyers as a mordant, and to neutralize various acid agents; a tartrate of tin is also prepared from it. Argol, also called *Tartar*, is a bitartrate of potash. When purified and crystallized it is called *Cream of Tartar*, and is much used medicinally.

More than 1000 tons of argol are annually imported into this kingdom. It comes to us from almost all wine-producing countries. The best comes from Bologna and Leghorn; Rhenish fetches a lower price. Argol is now admitted duty free. Its price at present in the wholesale market is 30*s*. to 50*s*. per cwt.

ARGYLE can put forth very few pretensions to notice in an industrial point of view. It occupies a position on the western coast of Scotland rather out of the ordinary commercial route. Yet it is not without mineral riches. There are lead mines in several parts of the county, copper in Islay, and coal in Mull and Campbeltown. The slate-quarries of Easdale island have been among the most considerable in Britain; and there are quarries at Balaclulish in Lorn. Eight million slates have been procured from the county in one year. The marble and limestone of the county are of fine quality. The granite quarried near Inverary takes as fine a polish as marble; and the *lapis ollaris* (a kind of micaceous slate), with which the Duke of Argyle's castle at that place is built, is one of the handsomest of the building-stones found within the borders. Strontian, cobalt, and coral, occur in or near the county.

The manufactures of this county are unimportant. The woollen manufacture was established at Inverary, and carried on for many years under the patronage of the Duke of Argyle, but it does not seem to have flourished, and has been given up for some time. The cotton manufacture has gained but little ground; whatever is carried on is about Campbeltown. A more important branch of industry is the herring, cod, and ling fishery; the fish are both good and abundant, and the fisheries employ a great number of men. The chief trade of Campbeltown is in whiskey, the parish containing numerous distilleries.

ARIE'GE. The inhabitants of this department of France, besides the usual agricultural pursuits, are engaged in the manufacture of coarse woollens, linen, soap, hats, combs, porcelain, and pottery. There are also many tan-yards, paper-mills, saw-mills, glass-works, and numerous establishments for smelting iron and copper ores. The principal article of export from the department is iron, which is carried on the backs of mules to Auterive in Haute Garonne, whence it is conveyed down the Ariège to the canal of Languedoc and the Garonne. Wool is largely imported from Spain, which receives in return woollen fabrics, linen, cattle, and wax. Other articles of commerce are rosin, pitch, turpentine, cork, marble, medicinal herbs, and various miscellaneous products.

ARITHMETIC, as a science, does not

claim a place in this work; but a few useful rules and properties of numbers, applicable to the mechanical arts and to the details of every-day life, are given under various headings.

ARITHMETER, is another name for the ABACUS, sometimes employed in teaching children the rudiments of arithmetic.

ARITHMETICAL PROPORTION, is the relation which exists between four numbers, of which the first and second have the same difference as the third and fourth. Thus:—

$$1 : 2 \text{ and } 81 : 82$$
$$7 : 3 \text{ and } 16 : 12$$
$$2\tfrac{1}{2} : 3\tfrac{1}{4} \text{ and } 1\tfrac{3}{4} : 2\tfrac{1}{2}$$

are severally in arithmetical proportion, and in every such proportion the sum of the extremes is equal to that of the means. Thus—

$$12 + 7 = 3 + 16$$

ARKANSAS. This fine American river, the largest affluent (except the Missouri) of the Mississippi, has at the present time a commercial interest imparted to it by the proposed railway across America from the Atlantic to the Pacific. The Arkansas has its rise in the Rocky Mountains, and flows 2000 miles to the Mississippi; and one of the railway projects, suggested to the enterprising Americans by the discoveries in California and by the possession of Oregon, is to form a railway up the valley of this river, cross the range of the Rocky Mountains at the lowest available pass, and descend to the plains of Oregon and California. Whether this stupendous project will ever be executed, remains to be seen; in the mean time the Arkansas is a medium for bringing the produce of the West to the Mississippi and New Orleans.

ARKANSAS, one of the territories of the United States which lie westward of the Mississippi, is too young in civilization to present an important figure in manufactures and industry. It is however progressing rapidly. The chief produce is Indian corn, wheat, rye, oats, potatoes, cotton, wool, tobacco, and hay. It has numerous tanneries and manufactories of leather, distilleries, and flour-mills.

ARKEEKO, a sea-port on the western coast of the Red Sea, exhibits to us the mode in which the products of Arabia and Persia reach Abyssinia. The goods are landed at Arkeeko, where the kafilas or caravans assemble. From Arkeeko the kafilas journey in a southward direction, passing over the Taranta mountains, and proceed to Dixan, the first Abyssinian town on that side, and thence to Adowa, the chief mart of trade in the kingdom of Tigré.

ARKWRIGHT, SIR RICHARD, is so intimately associated with the progress of the mighty cotton manufacture in this country, that that history could not be understood without a notice of his inventions and improvements.

Born in 1732 at Preston, of parents too humble to give him anything more than a very slight education, Arkwright had to earn his living, first as a barber, and then as a dealer in hair. But his mind was busy all this time. To use Carlyle's quaint language —'Nevertheless, in stropping of razors, in shaving of dirty beards, and the contradictions and confusions attendant thereon, the man had notions in that rough head of his! Spindles, shuttles, wheels, and contrivances, plying ideally within the same; rather hopeless looking, which, however, he did at last bring to bear. Not without difficulty.'

Conflicting statements render it difficult to trace the history of the machinery by which Arkwright so greatly improved the cotton manufacture. It is, however, certain that in 1767 he employed a clockmaker named Kay, then residing at Warrington, to make a model, which was speedily followed by a working machine. This machine was first set up at Preston; but, fearing to encounter such riotous opposition as had been called forth shortly before by the introduction of Hargreaves' spinning-jenny, Arkwright removed it to Nottingham, where he obtained pecuniary assistance from the Messrs. Wright, bankers, and shortly entered into partnership with Messrs. Need and Strutt, eminent stocking-manufacturers of that town. By this important connection the mechanical skill of Mr. Jedediah Strutt, who invented the contrivance by which Lee's stocking-frame was adapted to the production of ribbed stockings was brought to bear upon certain deficiencies of the machine with great advantage. In 1769 a patent was obtained for the machine, the most important feature of which was the use of two pairs of rollers, technically called *drawing rollers*, the first pair revolving slowly in contact with each other, and the second pair revolving in like manner, but with greater velocity. The lower roller of each pair was fluted longitudinally, and the upper one covered with leather, and the two were pressed together with a gentle pressure by means of weighted levers, in order that they might take sufficient hold of the soft cotton passed between them. The fibres of the cotton-wool were first laid smooth and straight, by *carding* or combing, so as to produce a soft loose ribbon or cord called a *sliver*, the end of which was introduced between the first pair of rollers. In passing between them it received no further change than a slight compression, but as from them it was conducted to the second pair of rollers, moving with twice, thrice, or more times the velocity of the first pair, it was extended or drawn out to two, three, or more times its original length, its thickness being reduced in like proportion. As this action is effected by the sliding of the fibres upon one another, the distance between the two pairs of rollers must be so adjusted, in relation to the average length of the fibres, that the two pairs may never have hold of one fibre at the same time. Such is the beautifully simple principle upon which, with the aid of twisting, the thick soft sliver or carding is converted into a fine, hard, and compact yarn or thread.

Arkwright's spinning-machine was, in the first instance, worked by horse power; but in 1771 the partners built a spinning mill for working by water-power at Cromford, in Derbyshire, from which establishment, 'the nursing-place,' as it has been styled, 'of the factory opulence and power of Great Britain,' the machine took the name of the *water-frame*, and the yarn produced by it that of *water-twist*. It was in the arrangement of this establishment, the first of its kind, that Arkwright manifested that extraordinary talent for mechanical contrivance and adjustment, and for the no less difficult task of training human agents to take their places as part and parcel of a vast and complicated automatic apparatus, which earned for him the title of father of the factory system.

Notwithstanding the superior quality of the water-twist over other yarns, a superiority which rendered it available for use as warp, the prejudiced manufacturers formed a combination to oppose its use, and thus compelled Arkwright and his partners to commence the manufacture of it themselves, first into stockings and afterwards into calicoes similar in quality to those now used.

The invention of the machine for spinning by rollers was followed up by various improvements in the mechanism for carding and for other processes in the cotton manufacture, for which Arkwright obtained a second patent in 1775. As, however, the cheapness and beauty of the new cotton fabrics had by this time led to an extensive demand, the hostile manufacturers altered their tactics, and instead of endeavouring to put down Arkwright's inventions, they soon began to dispute his claim to them, and to appropriate them in defiance of his patent rights. The use of his new mechanism was extended in the course of a few years, by licences granted by the patentees, to a very great extent, and this circumstance rendered piracy more easy. In 1782 Arkwright computed that the new manufacture already employed upwards of 5000 persons, and a capital of 200,000*l.* In some cases the new machinery was destroyed by mobs, connived at, if not encouraged, by the higher and middle classes; while in others the unauthorized use of it without payment to the patentees was carried to a great length. He became involved in costly litigation, during which attempts were made to deprive him of the fame resulting from his inventions; the result has been to give merited praise to one or two earlier inventors who had languished in obscurity, but leaving quite enough to justify the high fame which Arkwright had achieved.

Prosperity continued to attend the establishment of Arkwright and his partners, notwithstanding the adverse decisions of the courts. His partnership with Mr. Strutt terminated in 1783, after which time he retained the works at Cromford, which were subsequently carried on by his son, while Mr. Strutt continued the works at Belper, which were founded about 1776. How greatly the cotton manufacture extended under the stimulating effect of his improvements may be conceived from the fact that the imports of cotton-wool, which averaged less than 5,000,000 lbs. per annum in the five years from 1771 to 1775, rose to an average of 25,443,270 lbs. per annum in the five years ending with 1790.

Arkwright was a very early riser; devoted himself most assiduously to business; was a severe economist of time; was exceedingly sanguine in his disposition; and entertained an unbounded confidence in the wealth-producing powers of machinery and manufactures. To his credit it is recorded that when upwards of fifty years of age he made strenuous efforts to retrieve the deficiencies of his early education; redeeming time from the hours usually devoted to sleep in order to apply one hour a day to grammar, and another to writing and orthography. In 1786, on occasion of presenting an address to George III. after the attempt on his life by Margaret Nicholson, he received the honour of knighthood; and in the following year he served as high sheriff of Derbyshire. He died in 1792, leaving property to the extent of half a million sterling; and his son Richard, who died in 1843, is said to have been the richest commoner in England.

ARLES. The situation of Arles on the banks of the Rhône gives it considerable advantages for trade. There is also a navigable canal, which runs from the Rhône to the sea. The corn, wine, fruits, manna, cattle, soda, salt, wool, and oil, of the surrounding country, find sale at Arles; and several manufactures are carried on, as of glass bottles, soap, silk, tobacco, and brandy. Arles has a very active coasting trade: merchant steamboats ply regularly to Marseille, and passenger steamers up the river to Avignon, Lyon, and Seyssel; about 100 vessels, of from 30 to 180 tons, are constantly under weigh for Marseille or Toulouse.

ARMAGH, one of the north-eastern counties of Ireland is one of the seats of the flax and linen manufacture, which is chiefly in the hands of the small farmers. Cotton is also manufactured, but not to any great extent. Spinning machinery has been introduced in a very limited degree.

ARME'NIA. However important Armenia may be in a geographical and historical sense, its industrial and commercial features are soon enumerated.

Armenia produces abundance of excellent iron and copper, which are exported to Mosul. Rich mines of gold and silver exist near Kebban and Argana, in the two branches of the Taurus which inclose the valley of Karpoot (anciently Sophéne), through which the Euphrates passes in its way from Armenia to Syria; rock salt abounds in the valley of Kulpia, which slopes towards the Araxes, four miles below the fortress of Koor Ougley. A range of hills, bordering the valley on the east side, is apparently entirely composed of that mineral, and in the sides of these numerous excavations have been made.

The valleys of Armenia are fertile in grain, tobacco, manna, hemp, cotton, and in fruit-trees, particularly a large description of apple, and walnuts. The excellence of the Armenian cotton was noticed by Marco Polo.

ARMILLA, is a bracelet, or large ring, for the wrist or arm. The wearing of the armilla, or bracelet, as an ornament, is of very high antiquity. It occurs in Genesis, chap. xxiv., 22, 23, where Abraham sends his servant to seek a wife for Isaac. The Amalekite who slew Saul (2 Sam i. 10) 'took the crown that was upon his head, and the *bracelet* that was on his arm,' and brought them to David. The armilla is often mentioned by the Roman writers, and it was worn both by males and females. It was also used as a reward for military bravery.

The Hamilton, Townley, and Knight collections of antiquities, in the British Museum, contain armillæ in great quantities, and of almost every variety of form, in gold, in silver, and in bronze.

These armillæ are interesting in an industrial point of view, in so far as they illustrate metallurgy in early times.

ARMOUR, is a general term for any defensive habit worn to protect the wearer from the attack of an enemy. *Harness* is a name formerly applied in this country to armour in the aggregate.

Some of the earliest manufactures in metal were connected with the making of armour. In the Bible we find the shield, helmet and breastplate mentioned at a very early period; and *greaves*, or armour for the legs, are named among the armour of Goliath. Homer mentions them, and his descriptions of the breastplate of Agamemnon, the shield of Achilles, and the golden armour of Glaucus indicate the highly decorated character of much ancient armour.

The complete Roman armour consisted of the helmet, shield, lorica, and greaves. The lorica was originally of leather, but in the time of Servius Tullius the whole of the Roman body armour was of brass. The Roman lorica was frequently enriched with embossed figures. Each Roman legion had its own device marked upon its shields.

The early Britons appear to have used no armour except the shield; but many of the Anglo-Saxons wore loricæ of leather and four-cornered helmets, having probably derived them from the Romans. The Anglo-Saxon soldiers appear in drawings of the eighth century with no armour besides the shield and helmet, and armed with the sword and spear. Towards the close of the ninth century the *corium*, or *corietum*, was the armour generally used. It was formed of hides cut into the resemblance of leaves, and covering one another. The weight of the ringed byrne seems to have been found a great impediment to activity. Edward the Confessor appears on his great seal in a diadem evidently put upon a helmet. The casque worn by the nobility was of metal, and of a pointed conical shape, but ornamented with gold and jewels, and in the later specimens furnished with a *nasal*, or small projecting piece to shield the nose.

The Danes, on their first appearance in England, seem to have had no armour beyond a broad collar or thorax of flat rings and leather greaves or rather shin-pieces; but about the time of Canute they adopted, probably from the Normans, a tunic with a hood and long sleeves, and *chausses*, or pantaloons, which covered the feet, all of these being coated with perforated lozenges of steel, called from their resemblance to the meshes of a net, *macles*, or *mascles*. They wore also a rounded conical helmet, or skull-cap, with a round knob, under which were painted the rays of a star on its apex, and a large broad nasal, to which the hood being drawn up over the mouth, was attached, so as to leave nothing but the eyes exposed. The shield remained as before, and the weapons were spears, swords, and battle-axes, or bipennes.

From the period of the Conquest, seals, especially those of our kings, and monumental effigies, furnish abundant evidence as to the changes which took place in the fashion of armour. The Conqueror himself appears on his seal in a hauberk apparently of rings set edgewise; and in the Bayeux tapestry ring-armour forming both breeches and jacket at the same time is represented. The *chapel de fer*, which resembles in shape a Tartar cap, being a cone which projects beyond the head, appears for the first time upon the seal of Rufus; and *tegulated armour*, which consisted of little plates covering each other in the manner of tiles, and sewn upon a hauberk, without sleeves or hood, appears during the reign of Stephen, towards the close of which the nasal of the helmet seems to have been disused. Henry II. is represented on his seal in a flat-ringed hauberk, and a conical helmet without a nasal. *Pourpointerie*, or *pourpointing*, which consisted of padded work elaborately stitched, appears first in the great seals of Henry III., where the hauberk and chausses appear to be of this description. Some changes appear also in the helmet, which, in his second seal, is cylindrical. *Poleyns*, or coverings for the knees, were worn in this reign. Archers are shown in illuminations of this period wearing leathern vests over hauberks of edge-ringed mail. Armour of interlaced rings, which did not require to be sewn to an under garment, and was probably introduced from the east by the crusaders, was introduced in this reign; in which also the *chanfron*, or armour for the horse's head, appears for the first time.

Considerable improvements were made in armour during the reigns of Edward I., II., and III. *Ailettes*, or shoulder-pieces; mixed armour, partly of plate and partly of mail; *armures de fer*, or richly adorned plate-armour; *mamelieres*, or pieces put upon the breast, and from which chains descended, one to the sword-hilt, and the other to the scabbard; the *cointisse*, or surcoat, ornamented with the warrior's arms, over the armour; moveable visors attached to the *bacinets*, or bason-shaped skull-caps,—all appeared during these three reigns. Increased ornament was a characteristic of the armour of the reigns of Richard II. and Henry IV., about which time Italian armourers were much employed by the English nobility. Chain-mail appears to have been entirely disused soon after 1400, complete armour of plate superseding it. Black armour was often used at this period for mourning. Plate-armour attained its highest perfection about the reign of Richard III., and one of the finest suits preserved in the Tower of London, accompanied by a chanfron, manæfaire, and poitral. for arming the horse, belonged to Henry VII. In his reign fluted armour was occasionally used; and in that of his successor armour was frequently stamped or engraved with arms and devices, and sometimes *damasquinée*, or inlaid with gold.

The use of complete armour began to decline in this country after the time of Elizabeth. The late Sir S. Meyrick's collection of armour at Goodrich Court is perhaps the finest private collection in this country. At the Mediæval Exhibition of 1850, many fine specimens of armour belonging to the feudal ages were collected.

ARMS. The few details which may be deemed fitting on this subject, in the present work, will be found under such headings as ARTILLERY, BOW, CANNON, GUN, RIFLE, SWORD, &c.

ARNOTTO, or ARNATTO, the inspissated extract from the fruit of the *Bixa Orellana*, is used by dyers to give a bright orange colour to silk goods, and to give a deeper shade to simple yellow colours. It is further used in many of our dairies to give a reddish colour to cheese, which it does without adding any disagreeable flavour or unwholesome quality. The Arnotto of commerce is brought to us from South America. It is moderately hard, brown on the outside, and of a dull red within. It comes in cakes of about two or three pounds weight each, and is generally enveloped in large flag-leaves previous to being packed in casks. In this state it receives the name of flag arnotto, to distinguish it from a less known variety called roll arnotto. Arnotto dissolved in potass and water forms Nankin dye; and most of its solutions are effected with alkalies. A varnish is made from it with alcohol.

The consumption of arnotto has been much increased in this country of late years. In 1847 about 270,000 lbs. were imported. Arnotto is now admitted duty free. It sells at present from 10*d*. to 1*s*. 10*d*. per lb.

ARNOTT'S STOVE. Dr. Arnott has distinguished himself by many ingenious contrivances, brought forward by him—not for the sake of profit, but as conducive to general health and comfort. The Water-bed, the Stove, the Ventilator—all are familiarly known by the name of the benevolent physician who invented them.

Arnott's Stove is one of the many varieties of *close* stove, in which the cheerfulness of an open English fire is abandoned for the sake of a more efficient mode of burning the fuel. It was in 1838 that Dr. Arnott published his work on *Warming* and *Ventilation*, in which he so beautifully and simply explains the philosophy of the fire-place. He shows how, in a common open fire we waste a large amount of fuel, heat our rooms very unequally at different distances from the fire-place, cause cold draughts to flow in from the doors and windows, and a stratum of cold air to lie next the floor and near the feet, leave the rooms without good ventilation, occasion much unnecessary smoke and dust, waste much time in attending to the fire, entail danger to person and to property, and necessitate frequent cleaning of chimneys. It was to remove some of these evils, and to lessen others, that he suggested his new form of stove—the guiding principle of which is, to allow the fuel to burn very slowly, through the controlling agency of a valve for admitting the air. The stove usually consists of an exterior iron case, square or cylindrical, lined with fire clay; the fuel is burned in a box or vessel within the case; there is one opening in the outer case to admit fuel, another to remove ashes, and a third at which a flue may be fixed to carry off the products of combustion. All these apertures being closed, air must enter to feed the fire in some other way. This is admitted by a very small aperturo near the level of the burning fuel; and the aperture is closed by a valve which forms the distinguishing feature of the Arnott stoves. Many varieties of the valve have been adopted; but all of them are *self-acting*. When the fire is too fierce, the valve closes automatically, and refuses to admit any more air until the heat becomes subdued; but under average circumstances the valve remains open, and a small but steady stream of air enters the stove. The most successful contrivance is found to be a tube containing mercury, placed within the outer case, and bending round to the exterior in the form of an inverted siphon; when the mercury becomes heated, it expands, rises in the tube, and thus moves a small piece of apparatus which governs the valve.

The relation which Arnott's stove bears to stoves and heating apparatus generally, is noticed under WARMING AND VENTILATING.

ARNOTT'S VENTILATOR. Dr. Arnott's contrivances in respect to heat and air all depend on these two points—how to bring pure air *into* a room and a fire; and how to expel impure air *from* a room and a fire. The Ventilator, now happily so much used in ordinary rooms, is an exceedingly simple means of effecting the second object. When the cholera was raging in London in 1849, Dr. Arnott suggested that, in every badly ventilated room, a brick should be taken out of the wall near the ceiling, so as to open a direct communication between the room and the chimney; and he wrote a letter to the *Times*, in which the rationale of this contrivance was described with a clearness and simplicity which few but himself can effect by words alone. He said, 'Every chimney in a house is what is called a *sucking* or *drawing air-pump*, of a certain force, and can easily be rendered a valuable ventilating pump. A chimney is a pump—first, by reason of the suction or approach to a vacuum made at the open end of any tube across which the wind blows directly; and secondly, because the flue is usually occupied, even when there is no fire, by air somewhat warmer than the external air, and has, therefore, even in a calm day, what is called a chimney-draught proportioned to the difference. In England, therefore, of old, when the chimney breast was made higher than the heads of persons sitting or sleeping in rooms, a room with an open chimney was tolerably well ventilated in the lower part, where the inmates breathe.' But modern fire-places are made low, and the heated air cannot thus escape. 'If, however, an opening be made in a chimney-flue through the wall near the ceiling of the room, then will all the hot impure air of the room certainly pass away.... For years past I have recommended the adoption of such ventilating chimney openings; and I devised a balanced valve, to prevent, during the use of the fires, the escape of smoke to the room.'

Such is the philosophy and the action of the ventilating valves. They are made rectangular or circular, of iron or of brass, plain or ornamental, balanced in front or behind; but all act alike on the same principle.

Dr. Arnott has devised other and more elaborate ventilators. He was applied to by the Board of Health, a year or two ago, to suggest means for the ventilation of ships; and he has described very efficient means of attaining this end. Quite recently (1850) he has planned a system of ventilation for a large building of a highly curious and scientific kind. The building is the York County Hospital, which has a reservoir of water at a height of 60 feet from the ground; and he resolved that this water should work the apparatus for ventilating the whole building. A large circular vessel has been constructed, which is partly filled with water; floating on the water, or rather resting with its edges on the water, is a kind of gasometer, or inverted air-chamber. A pipe of small diameter extends vertically from the water vessel to the reservoir at the top of the house; and the water, flowing down this pipe, exerts a great hydraulic pressure on a piston, which forces the water into the gasometer, and forces the air from the gasometer into air-passages which ventilate the building. The scientific principles of the hydraulic press, of the air-pump, and of the gasometer, are all involved in the arrangement. The gasometer holds 125 feet of air; it is filled and emptied by the action of the apparatus, sixteen times in a minute; so that 2000 cubic feet of air per minute are forced into the ventilating passages of the hospital.

The general subject of ventilation, in its varied forms, is noticed in the article before referred to. [WARMING AND VENTILATING.]

ARO'MA AND AROMATICS. Aroma is the supposed principle of odour in plants, formerly called by Boerhaave *Spiritus Rector*. This quality generally resides in the essential oil; but there are some vegetables that have a strong odour which yield but little or no essential oil, as the jessamine and the violet; or when an oil in small quantity is procured from them, it has not a powerful smell.

Aromatics exercise a peculiar influence over the digestive powers, and are possessed of more or less odour or fragrance. Of this odour, by which they can at all times be recognised, the most usual vehicle is an essential or volatile oil, as just stated. Indeed, volatile oil exists in all aromatic plants, and in every part except the cotyledons, save in the nutmeg and a very few other seeds; but this aromatic oil does not reside in the same part in every kind of plant.

Aromatics are seldom applied to the organ of smell for the purpose of influencing the system in a remedial manner, but are usually introduced into the stomach. As all aromatics contain volatile oil, their action is generally referred to this principle; but there cannot be a doubt that the more fixed principles which they contain contribute greatly to their effect. Volatile oils, when separated, act chiefly on the nervous system; but aromatics influence the digestive organs, the function of assimilation, and the circulation. The necessity for the employment of aromatics is greater in warm climates and weather than in cold; and we find the plants which furnish them grow in the greatest abundance in hot countries. Throughout the East Indies the natives restore the powers of the stomach by chewing betel, which consists of slices of the areca nut, sprinkled with fresh lime, wrapped up along with some aromatic in a leaf of the *piper betel*. The Indians of South America use the *Erythróxylum Peruvianum* (called *coca*) along with the leaves of the *Chenopódium Quinoa*, mixed with quicklime, to stimulate the impaired powers of the stomach during their long and toilsome journeys over the heights of the Andes. On the same principle, the Europeans who visit tropical countries use curry and other hot dishes. But in every quarter of the globe we find condiments used along with all articles difficult of digestion, especially vegetables, fish, and young meat, such as veal.

ARPENT. The arpent is one of the French measures of land, intended to be abolished by the metrical system, but still given in various books, and therefore useful to be known. There were, however, four varieties of it; the smallest of which contained 4089 English square yards, and the largest 9770. The crown-lands were measured by the arpent of 6107 English square yards—about 1¼ acres.

ARQUEBUS. This variety of fire-arms, now out of use, was a sort of hand-gun, provided with a small apparatus suggested by the trigger of the cross-bow, to convey with certainty and quickness the burning match to the touch-powder.

The arquebuses made in the 15th century were often very ornamental. At the exhibition of Mediæval Art, in 1850, many such specimens were collected. In one example, belonging to the Board of Ordnance, the stock is inlaid with ivory, the bow is engraved with arabesques partly gilt, and the linstock is engraved with figures of seven deities.

ARRACK. [ARACK.]

ARRAGON. [ARAGON.]

ARRAGONITE. These crystals have been found abundantly in a ferruginous clay in Aragon in Spain, where they occur accompanied by sulphate of lime; and they are also met with in numerous other parts of Europe. Arragonite is a carbonate of lime, chemically almost identical with calc-spar; but of different crystallized form, heavier and harder than that substance.

ARRAN, the rugged island lying off the coast of Ayrshire, in Scotland, affords a few of the crude materials of industry. It has its quarries of white sandstone; a small supply of slate; a little coal (too limited however to repay for working at present); while wanderers over its mountains often pick up transparent stones, worked by the jewellers under the names of Arran stones, cairngorms, and Scotch topazes. There is a manufactory of sulphate of barytes, used in making paint.

ARRIS, in French *Areste* and *Arête*, is a term employed in building to express the intersection or line in which the two straight or curved surfaces of a body, forming an exterior angle, meet each other. The term is synonymous with edge; but the term edge only is used in reference to parallelopipedal bodies, on which the length and thickness may be measured.

ARRIS FILLET, a small triangular piece of wood, used to raise the slates of a roof against the shaft of a chimney or a wall, to throw off the rain more effectually; it is used for the same purpose also in forming gutters round skylights, which have the same inclination as the roof, and are slightly raised above it.

ARROBA, is the name both of a weight and a measure, in Spain, Portugal, and the Canaries. The weight-arroba varies from about 25 to 33 lb. avoirdupois; the measure-arroba varies from 2½ to 3½ gallons.

ARROO, a large island near New Guinea, is a trading depôt for the Chinese, who procure from Arroo pearls, tortoise-shell, edible birds'-nests, and an aromatic bark named missoy, which resembles cinnamon. Birds of paradise are very numerous in these islands: they are caught by the natives for their plumage; their flesh, when preserved by fumigation, is bought by the Chinese traders.

ARROW. [Bow.]

ARROW-ROOT is a farinaceous substance prepared from the roots or tubers of various plants; that from America and the West Indies being the produce of *Maranta arundinacea* and *Maranta indica*, and that from the East Indies being from the *M. indica*, and from several species of *Curcuma*. Among other plants which yield a similar substance is the cuckoo-pint, *Arum maculatum*. Arrow-root is prepared by either grating or beating the tubers in a mortar to a pulpy consistence; separating the fibrous matter from the pulp by mixing it with a quantity of water, and passing it through a hair-sieve; and then suffering the pure farina to subside from the remaining milk-like fluid, and if needful, purifying it still further by successive washings and strainings. The moisture is at length evaporated by exposure to sun and air, and when perfectly dry the powder is packed in boxes or casks, in which state it may be kept for many years. West Indian arrow-root is usually of a pure white, and East Indian has a yellowish tinge. Its taste is insipid, and the powder emits a crackling sound when pressed in the hand, and retains the impression of the fingers, which common wheat-starch does not. Being very easy of digestion, arrow-root constitutes a valuable article of food for children and delicate persons. It is used mixed with boiling water or milk, or in the form of puddings, and may be given plain, or with wine or spices. Potato-starch is not so digestible, and, if prepared from potatoes in the spring, is liable to disturb the stomach. The common English name of this preparation is derived from the use to which the South American Indians applied the roots of a plant once confounded with the Maranta, but now called *Alpinia galanga*, as an antidote to the effect of poisoned arrows.

It is said that a very large portion of that which is sold in the shops under the name of arrow-root consists of potato-starch.

The cultivation of arrow-root has lately been introduced with considerable success into the island of St. Vincent. Machinery of skilful construction is employed to prepare the arrow-root from the plant; and the packing for shipment is very carefully conducted.

Arrow-root from British colonies pays 6d. per cwt. import duty; from foreign countries 2s. 6d. In 1847 about 10,580 cwts. were imported; and in 1848 about 8,100 cwts.

ARSENAL, a public establishment where naval and military engines, or warlike equipments, are manufactured or stored. The Royal Arsenal at Woolwich is the chief establishment of this kind in England. In France the chief arsenal is at Paris. Toulon, Marseille, and Brest, are naval arsenals.

ARSENIC is a peculiar metal, frequently met with in nature; sometimes in its pure metallic state, but more commonly combined with other metals, as iron and cobalt, or with sulphur, and frequently united with oxygen. Arsenic has a steel gray colour and considerable brilliancy; its density is about 5¼ times that of water. The native metal is granular, and the artificial crystalline; it is extremely brittle, and consequently easily powdered. When arsenic is exposed to the air, it soon loses its lustre, and becomes black on the surface. When kept under water, it undergoes no change; if heated to 356° Fahrenheit, it is volatilized, without previous fusion; the vapour has a strong smell, resembling that of garlic, and this, to a certain extent, is relied upon as proof of its presence; the vapour readily condenses in small brilliant crystals of metallic arsenic.

Arsenic and oxygen combine in two proportions, and both compounds possess acid properties; that which contains the smaller quantity of oxygen is termed *arsenious acid*, the *white arsenic* of the shops. *Arsenic acid*, which contains the larger quantity of oxygen, exists in nature much more commonly than the arsenious acid, in combination with lime, copper, iron, and lead. It is of a milk-white colour, and is very poisonous. *Arsenic and hydrogen* combine to form a gas, which, however, when subjected to intense cold, is condensed into a limpid liquid resembling æther. The gas has an extremely fetid smell. The *chloride of Arsenic* is a colourless volatile liquid, which combines with oil of olives and of turpentine, and partially dissolves sulphur and phosphorus when heated. *Arsenic and sulphur* may be made to combine in four different proportions; of which two yield *realgar* and *orpiment*. Realgar, a red sulphuret, is of a deep-red colour, brittle, easily reduced to powder, inodorous, tasteless, and insoluble in water. Orpiment, a yellow sulphuret, is commonly composed of thin plates, which are of a very fine yellow colour, and flexible to a considerable degree.

Arsenic and metals in general combine with great facility: those which are malleable it renders brittle, and those which are difficult to melt it renders fusible. These alloys do not form an important class of bodies.

The arsenic and arsenious acids combine with many alkalies and metals to produce salts. These, as well as other preparations of arsenic, are largely used in the arts. Arsenite of potash is used in making cobalt blue; the red sulphuret is used in making fireworks; the yellow sulphuret is used as a dye, as a pigment, and in making fireworks; arsenic in its metallic state is employed for a few purposes, generally in an alloyed state. The *medical* applications of arsenial compounds we do not notice here; further than to say that the common arsenic of the shops is arsenious acid, and that it is too frequently adulterated with plaster of paris and other cheap substances.

The late Mr. Marsh devised some extremely delicate means of detecting the presence of arsenic. The liquid suspected to contain the poison is acidulated with sulphuric acid and placed in contact with metallic zinc, both of which must be previously ascertained to be free from arsenic; if any arsenic be present in the liquid, the hydrogen gas generated reduces and dissolves it, forming arsenuretted hydrogen gas. This gas is to be lighted at a jet, and a piece of white porcelain or of glass is to be held over the flame, when, if any arsenic be present, a brilliant black spot of metallic arsenic is deposited on the glass or porcelain. Another method of proceeding is to boil a slip of bright metallic copper in the fluid suspected, previously acidulated with hydrochloric acid. If arsenic be present, the copper is covered with a whitish alloy, and then by heating the metal in a test tube, the arsenic is volatilized, and sublimes in the metallic state in the cold part of the glass. This method is susceptible of detecting very minute portions of arsenic.

Foreign arsenic may be imported into this country duty free.

ART-UNIONS are societies for the encouragement of the fine arts by the purchase of works of art out of a common fund raised in small shares or subscriptions; such works of art, or the right of selecting them, being distributed by lot among the subscribers or members. The success of similar associations in Germany and Prussia led to the establishment in 1837 of the Art-Union of London, which, though it has given rise to many others, remains at the head of such societies in this country. In it every member subscribes annually the sum of one or more guineas, receiving accordingly one or more shares in the advantages held out. Part of the sum thus raised is expended in the engraving of one or more works of art, of which every subscriber receives a copy; but, though the prints thus distributed are such as would, in the ordinary course of trade, cost the full amount of the subscription, they are, owing to the combination of a very large body of subscribers, and the avoidance of risk, produced at so small a cost as to leave the greater part of the subscribed funds available for the purchase of original pictures or pieces of sculpture. The sum thus appropriated is divided into prizes of from 10*l.* to 300*l.* or 400*l.*, which are distributed by lot among the subscribers; the prize-holders being allowed, under certain restrictions, themselves to select works of art to the specified amount. These works of art, previous to their delivery to the prize-holders, are gratuitously exhibited for three or four weeks to the subscribers and the public.

In the season of 1850 the subscriptions amounted to 11,180*l.*; the sum laid out in the purchase of pictures, statuettes and medals was 5073*l.*, and on engravings and etchings 3250*l.* The works of art selected by the subscribers amounted in number to 1021.

Doubts having been raised as to the legality of art unions, temporary acts were passed in 1844 and 1845 to indemnify their managers from the penalties to which they were supposed to be subject; and in 1846 an act (9 & 10 Vic. c. 48) was passed to legalize such as have been or may be incorporated by royal charter, or may have their rules and deed of partnership approved by a committee of the privy council. The Art-Union of London was incorporated by royal charter on the 1st of December, 1846.

ARTA, a town of Albania, holds a respectable rank in respect to manufactures. In the quarter set apart for trade, each art has its separate street or bazaar, and articles of dress manufactured here are held in high estimation. The floccatas, or shaggy capotes of Arta, are considered the finest; woollens, coarse cottons, and Russia leather, are also manufactured, and this town derives some commercial benefit as the entrepôt between Joanina and the gulf, by which the produce of Albania reaches the sea.

ARTESIAN WELLS are perpendicular perforations or borings, through which water rises from various depths, according to circumstances, above the surface of the soil. Such perforations have been named Artesian wells, from the opinion that they were first used in the district of Artois in France. They are seldom more than a few inches in diameter, and are made by means of the usual boring instruments. Their action is due to the constant endeavour of water to seek its level.

Let us suppose, for example, that there is an undulating tract of country, with a town placed in a hollow or valley. Near the surface is a thick bed of rock or clay, either impervious to water, or through which it percolates with difficulty. Beneath this is a sandy or porous stratum which 'crops out' or appears at the surface, on certain heights beyond the limits of the town. Beneath this stratum, again, is a close or impervious one. Under these supposed conditions the rain-water, falling on the heights, is absorbed by the 'crop out,' and filters down through the sandy stratum entirely beneath the town: unable to leave that sandy film or layer, because the strata above and below are nearly impervious to water. If, under these conditions, a perforation be made near the town, deep enough to reach the sandy stratum, the water which saturates this sand, the water will rise through the hole—not merely to a level with the town, but will often spout up far above that level, according to the height of the ground where the 'out-crop' of the sandy stratum occurs.

This is the principle of the Artesian well, let it be carried out how it may. The geologist has to determine whether a watery stratum probably exists: the well-borer has to devise the mode of reaching it.

One of the most celebrated Artesian wells is that at Grenelle, near Paris. It was commenced in 1833, and not finished till 1841. Geologists were aware, from the nature of the formation beneath and around Paris, that any watery sandy stratum must necessarily be at a great depth; but the urgent want of water for the supply of the south-western portion of Paris, determined the authorities to brave all difficulties in the attempt. The boring proceeded slowly, interrupted from time to time by disasters which severely taxed the patience of the engineer. At length, in February 1841, the boring rods suddenly penetrated into the watery stratum; and a stream of pure and limpid water rushed up to the light of day, from the subterranean depths where it had been so long buried. The depth to which the boring was carried exceeded 1800 feet.

In 1837 the inhabitants of Southampton, requiring an improved supply of water, caused an experimental boring to be made on an elevated common about two miles north of the town. The result being deemed satisfactory, measures were taken for the sinking of a shaft. It proved an enormous work. The well-diggers penetrated through 78 feet of alluvium, 300 feet of stiff clay, 100 feet of plastic clay, and about 100 feet of chalk: encountering much difficulty in forming a substantial open shaft. Having thus reached a depth of about 580 feet, the boring rods were used, and were driven to a further depth of more than 700 feet; so that the total depth attained exceeds 1300 feet. The labour and expense were ultimately rewarded; for a flow of 50,000 gallons of water per day was obtained. The expense was nearly 20,000*l*.

The Artesian Wells of Grenelle in France, and Southampton in England, may be taken as types of these works on a large scale. Nearly all the others which have been formed are of less magnitude, and have involved less expense.

In a paper read before the Institute of British Architects by Doctor Buckland, in 1849, he drew attention to the fact that a well is not properly artesian unless the water overflows at the surface. Thirty years ago there were several such wells in and about London; but such has been the exhaustion of the springs within this district, that there is now hardly a single well of such a kind, although there are about 300 which are called artesian, chiefly from the mode in which they are sunk by boring instead of digging. The water now obtained in London wells does not rise to within many feet of the surface, and expensive machinery is often necessary to make it available. In the artesian well which supplies the fountains in Trafalgar Square the water does not reach within forty feet of the surface, whence it is pumped up by a steam engine: the supply is good, but the process of obtaining it is costly. The level of the water in the London wells is gradually sinking, as the number of wells increase. Doctor Buckland estimated the present average level in the London wells at 60 feet below the surface, and he thinks that in twenty years it will have sunk to 120 feet. One of the great porter breweries has now to pump up water from a depth of 188 feet, in a well which a few years ago maintained a level 95 feet below the surface.

These observations, coming from a high authority, have had some influence on the recent discussions concerning the supply of London with water. Whatever may be the plan ultimately adopted, it does not seem that the artesian system would be fitting for such an enormous supply as would be necessary.

The mode of digging or boring for Artesian Wells is described elsewhere. [BORING.]

ARTICHOKE. The artichoke and the cardoon are two species of the same genus of plants. The artichoke came originally from the south of Europe, and though it has long been cultivated in the regions of the north, it does not resist the very severe cold of winter. The root of the artichoke is rather bitter, the stem still more so. It was formerly employed as a diuretic, but it has long been cultivated only as a kitchen-garden plant. The cardoon is found in the southern countries of Europe and in the north of Africa. When cooked it is tender, and its flavour greatly resembles that of the artichoke. It is in general a choice dish, and seldom seen except at the tables of persons in easy circumstances.

ARTIFICIAL FLOWERS. Few employments of a mechanical or manipulative nature are more beautiful in their results than the production of artificial or imitative flowers. Nothing can well exceed the faithfulness of these imitations; every petal, every leaf, every calyx, every bud, is imitated with an accuracy which must have required long observation and much ingenuity on the part of those who have practised this art. A lady may for a shilling procure one of these delicate productions, such as would be deemed a fitting ornament for her attire; but a curious enquirer might also find a shilling not ill-spent, merely for the instruction to be derived from a dissection of this flower, with a view to study its mechanical anatomy.

The petals of flowers are imitated by ribbons, feathers, silk-worm cocoons, cambric, taffeta, velvet, or thin laminæ of whalebone shaped and coloured for the purpose. The stems are mostly formed of wires, wrapped round with paper, silk, or some other material of the requisite colour. The leaves and petals are mostly cut and embossed by stamping with dies having sharp cutting edges, and are united together by means of wires and paste or cement. The modes of colouring are exceedingly various. Seeds and similar objects, and small fruits, such as currants, are imitated by wax, glass, and other substances. Very beautiful imitations of some plants are made with wax, rice-paper, and shells.

This manufacture is generally carried on in private houses, where a large number of persons (mostly females) work together, each taking certain departments, according to the principle of the division of labour; and the whole product is then sold to wholsale dealers, who supply the retail shops.

Our French neighbours are especially distinguished in this art; all their delicacy of taste is brought to bear upon it; and we may reasonably expect that the Great Exhibition of 1851 will afford a favourable display of their skill. M. Dupin, in his recent letter to the French manufacturers, says:—'Let us not forget a branch of trade which, assiduously studied, rivals nature itself; this is the production of artificial flowers in every possible variety. Of these, France sells to the extent of a million francs (40,000*l.*) to the foreigner; and England, with the United States, purchases more than half this amount.'

We will take a *rose*, as a specimen of French imitative manufacture. The petals, the leaves, the calyx, the buds, the stamens, the stalk—all require distinct processes. First, for the *petals*. These are made of the finest cambric, which is cut out with punches; there being as many different sized punches as there are different sizes in the petals of a rose. Each petal is held by pincers at the extreme end, dipped into a carmine dye, then dipped into water to soften the tint at the edges, then touched with a brush to deepen the tint near the centre; and any little variegated spots, or even blemishes, are imitated by tinting with a brush. Next for the *leaves*. These are made of Florence sarcenet, which is dyed to the proper colour, stretched while wet that it may dry out perfectly smooth; the glazed surface of the leaf is imitated by coating the sarcenet with thin gum-water; while the velvety texture of the under surface is imitated either by a wash of coloured starch water, or by a layer of *flock* or cloth powder, such as is used in making flock paper-hangings. To imitate the *ribs* which form such a peculiar and beautiful characteristic of the leaves, several leaves, placed one upon another, are pressed between *gaufroirs* or goffering-irons, cut with the required indentations. Then we have the leaflets which form the *calyx*; the sarcenet for these is stiffened with starch water while yet wet from the dyeing; and when dry, the material is cut to the proper size and shape by punches. The *buds* are made of sarcenet or of kid, dyed or painted according to circumstances; they are swelled out to the proper shape by a stuffing of cotton, gummed flax, or crumb of bread, and are tied with silk at the end of thin iron wires. The *stamens* are made of silk, fixed at the ends of brass wires, and so shaped that the wire shall imitate the filament and the silk the anther; the silk anther being dipped into a glutinous liquid, is made to retain some very small seeds which imitate the pollen. Lastly comes the building-up of the delicate structure; the stalk is made of iron wire, coated with cotton and green paper; and around this stalk are grouped and fastened the several parts which together form the imitative rose.

ARTIFICIAL FUEL. Some of the compositions, recently introduced as substitutes for coal, are noticed under FUEL.

ARTIFICIAL GEMS; ARTIFICIAL PEARLS. The principal methods adopted in imitating the costly gems which take such a high rank in respect to personal adornment, are described in a later article. [GEMS, FACTITIOUS.]

ARTIFICIAL LIMBS, &c. Considerable mechanical ingenuity is displayed in supplying substitutes for limbs or organs which accident or any other cause has removed.

The art of the dentist, for instance, calls for no small amount of mechanical skill. First there is the choice of the ivory which, from its colour, texture, and hardness, affords the best imitation of the natural teeth. Then there is the shaping of this ivory to the size and form of the tooth, whether single or double, front or back, upper or under. And lastly there are the remarkable contrivances —by means of golden palates, or springs, or wires, or cement, by which the tooth or mouthful of teeth are fixed in their places. Experience seems to shew that few kinds of cheapness are so dear as cheap tooth-making: so great are the difficulties in supplying teeth that will really eat their way through the difficulties presented to them. As for the *succedaneums* and metallic and other *cements* for stopping decayed teeth, their merit depends more on the quality of the material than on the mode of using. We see from time to time patents for new contrivances in dental surgery, which involve no small amount of ingenuity. One such has been enrolled in 1850 by Mr. Dinsdale, in which the manufacture of teeth, palates, and gums are described.

An artificial eye is an example of glass manufacture; the shaping of the glass being much less difficult than the accurate imitation of the cornea and iris by means of pigments and dyes.

All those numerous examples of skill, which may more fittingly be called surgical *operations* than anatomical *contrivances*, we have nothing to do with here; but when a mechanician undertakes to supply an arm, a hand, or a leg, which will render tolerable service as a substitute for one of flesh and blood, we have as much right to claim it as a proof of constructive skill as a loom or a lathe, a plough or a clock. And here we mark how quickly a newly discovered substance becomes brought within the scope of the operations. Is it caoutchouc? Then will the artificial legmaker find out where to use it with advantage. Is it gutta percha? Then will he soon see where the combined elasticity and toughness of that remarkable substance are likely to be valuable. Accordingly we find that many different materials are employed, either to give shape to the artificial hand, arm, or leg, or to give smoothness and softness to the surface, or to form the joints for the requisite movements. Wood, leather, caoutchouc, gutta-percha, cork, iron levers, steel springs—all are employed; and much ingenuity is displayed in arranging.

Sir George Cayley, who has exhibited much inventive talent in various mechanical contrivances, has recently made many trials to produce an artificial hand which shall be less costly than those ordinarily constructed. He has made the 'Mechanics' Magazine' the medium of communicating his experience in this matter. His first attempt was in 1845. The son of one of his tenants having lost a hand by accident, Sir George contrived a substitute which has in many ways lessened the severity of the privation. The movements of this instrument are derived from the stump; a light frame-work fixes the apparatus to the upper part of the arm; and a lever connects this frame-work with the artificial hand. The arm is placed within padded rings of metal, which are connected by two long steel bars hinged at the elbow. When the wearer moves his arm by the usual action of the elbow joint, he shifts a small metal bar near the wrist of the machine, which works two cog-wheels acting on each other; and these cog-wheels bring two steel springs together so as to enable them to grasp an object something in the manner of a thumb and fore-finger. The wheels and springs may either be left exposed, in the metallic state, or may be padded so as to represent a thumb and finger.

It was found that although this artificial hand could be turned round a little way, it could not be turned so much as a quarter of a circle from its horizontal towards a perpendicular grasp; and there was, at the same time, no movement equivalent to the usual bending of the wrist, which gives so great a variety of positions to the natural hand. He therefore contrived a new arrangement of mechanism at the wrist, so as to superadd these two movements to those before pos-

sessed by the apparatus; this involved an increase of rather delicate mechanism.

At one of the soirées given by the President of the Royal Society in 1845, the boy for whom Sir George Cayley made the artificial hand was introduced, and Prince Albert "shook" him by his mechanical appendage. The hand had only one finger worked by the mechanism; but there were the proper number of cork fingers united side by side, and fixed to one broad thin steel plate, jointed, and covered with continuous leather, stitched down to mark the distinction of the fingers under it. But where a more expensive apparatus can be afforded, and the appearance of having a real hand is sought for, the thin steel plate can be separated into digits, though united at the base as in a common hand, and jointed at the proper places in due proportion to each finger.

In another form of artificial hand, made by Sir G. Cayley, in 1847, there is a case or sheath, into which the stump of the arm is introduced. A spiral spring is fixed at one end to this sheath, and at the other to a bent lever; while the middle of the lever is connected with the mechanism of rods which move the artificial thumb and fingers. In this arrangement, the wearer uses his sound hand to work his artificial hand. He presses a little button which is connected with the bent lever; by pressing this towards the wrist, the fingers and thumb open to receive any object they may be intended to grasp; and when this pressure from the other hand is taken off, the grasp takes effect, without further effort, till released by a contrary movement. The mechanism is very simple, and is attached wholly to the lower arm, near the stump. But as the sound hand must be taken from anything else it has to perform, at the time the artificial hand is thus put to work; and as it may on other accounts be inconvenient to work the apparatus in this way, Sir George invented a very ingenious means of working the hand by the movement of the upper arm or shoulder-joint.

M. Magendie described to the Paris Academy of Sciences, in 1845, an artificial arm, invented by M. Van Petersen. A sort of stays are fixed round the breast of the person; and from these are brought cords made of catgut, which act upon the articulations, according to the motion given to the natural stump. The apparatus was found to be very effective. It was tried (among other patients) on an invalid soldier, who had lost both arms in the wars of the empire, retaining only the stumps. With the aid of two of the artificial arms, he was able to perform many of the functions which had hitherto been performed for him. M. Magendie considers this contrivance to be the best substitute for a natural arm yet introduced.

ARTIFICIAL STONE. [Cement.]

ARTILLERY. This term, since the introduction of gunpowder, has been applied chiefly to large ordnance, together with their ammunition and appurtenances.

The earliest military engines were, in all probability, those for casting large stones. Such machines do not appear to have been used in England until the Norman invasion, and were used by the Normans chiefly in sea-fights, for throwing Greek fire, quicklime, and other combustibles, as well as stones and darts. Richard I. employed against the Saracens some such engines, worked by the force of the wind acting upon sails. Edward I. used engines at the siege of Stirling Castle, in 1303, which threw stones of 300 lbs. weight.

The invention of gunpowder, though it did not for a long time supersede the ancient artillery, gradually brought about great changes in the art of war. The first cannon, which were called *bombards*, were very clumsy, wider at the mouth than the chamber, and formed of bars of iron bound together with hoops. The earliest cannon-balls were of stone. *Hand-cannon* carried by two men, and fired from a rest in the ground, were early used; and *carts of war*, conveying light artillery, are mentioned in a Scotch act of parliament in 1456. Cannon began to be formed by casting about the middle of the fifteenth century. Iron bullets (of which Monstrelet mentions one weighing five cwt.) began also to be used, but not to the exclusion of those of stone. A hard mixed metal, called *font-metal*, or *bronze*, was early invented for the casting of cannon; and the casting of this kind of ordnance was commenced in England in 1535. In the sixteenth century the size of cannon was reduced, and they were made of superior form. One of the largest cast cannon now existing is a brass one at Bejapoor, which was cast in commemoration of the capture of that place by the Emperor Alum Geer, in 1685. Its extreme length is 14 feet 1 inch; the diameter of its bore 2 feet 4 inches. An iron shot for this gun of proper size would weigh 1600 pounds.

For *mortars* we are indebted to workmen who were employed by Henry VIII.; those made for him about 1543 being, according to Stowe, 'at the mouth from 11 to 19 inches wide,' and employed to throw hollow shot of cast-iron, filled, like modern bombs, with combustibles, and furnished with a fuse.

Different names were given about that date to different kinds of cannon; such as *falcon*, *culverin*, *demi-culverin*, *minion*, and *sakar*. *Petards*, which are explosive engines employed in sieges, were first used by the Huguenots in 1580. The *howitzer*, an improvement on the mortar, was first used in 1697; and the *carronade*, a kind of long howitzer, about 1779.

The casting of these instruments of destruction is described under CANNON.

ARTIZANS. In this country it is customary when a young artizan has served his apprenticeship, for him to enter at once as a journeyman; to settle down in some town, usually where he has been apprenticed; and there work for any master who will employ him. Among the less respectable workmen, or when trade in general is dull, the *tramp* system is acted on; the artizan goes from town to town, a sort of homeless wanderer, seeking work wherever it may be found, and often forced to associate with disreputable companions.

But in Germany the custom is different. There a kind of tramp-system is not merely looked forward to, but is compulsory. The *wanderschaft* of a German workman is a transition period between the life of an apprentice and that of a master. In many parts both of Germany and Switzerland, an apprentice cannot obtain his freedom and become a master until he has spent a certain number of years in following his calling beyond his native country. He is furnished on setting out with a book called a *wander-buch*, in which his various employers insert certificates of his service and conduct. In his wanderings he is generally assisted and succoured, not only by the trade to which he belongs, but by the donations of travellers. Many English travellers in Germany must have encountered these young workmen, trudging along the roads, with knapsack on back. Mr. Symonds, ('Arts and Artizans, at Home and Abroad') states that, while certain evils arise from this system, it tends on the other hand to give the young men an amount of general information more varied and extensive than is commonly met with among English workmen.

In the Vorarlberg (a part of the Austrian dominions) the male inhabitants are accustomed to leave home early in the spring, go to Switzerland and France, exercise the trades of masons and house-builders during the summer, live with the utmost possible frugality, and return to the Vorarlberg in autumn with the savings of their labour.

The silk-weavers of Lyons have a very strict system of classification. There are small masters, workmen, and apprentices; besides the capitalist-manufacturers who set all to work. The masters, or *chefs d'ateliers*, are owners of a few looms, and have fixed residences. The workmen, or *compagnons*, have neither capital, looms, nor houses; they work the looms belonging to the master, live and board with him, and receive half the money gained by the looms they work—the other half going for house-rent, risk, wear and tear of machinery, &c. The *apprentices* are from 15 to 20 years of age; they are taught by the *chefs d'ateliers*, with whom and for whom they work.

Without entering far on this tangled subject, we shall notice, under CO-OPERATION, one or two of the recent suggestions for modifying the relations between employers and artizans.

ARTOCARPUS. [BREAD-FRUIT TREE.]

ARTS, FINE. The fine arts are generally understood to comprehend those productions of human genius and skill which are more or less addressed to the sentiment of taste. They were first employed in embellishing objects of mere utility, but their highest office is to meet our impressions of beauty or sublimity, however acquired, by imitative or adequate representation.

The great use of the arts is to humanize and refine, to purify enjoyment, and, when duly appreciated, to connect the perception of physical beauty with that of moral excellence; but it will at once be seen that this idea of usefulness is in a great measure distinct from the ordinary meaning of the term as applicable to the productions of human ingenuity. A positive use results indeed indirectly from the cultivation of the formative arts, precisely in proportion as their highest powers are developed. Again, as illustrating science, the fine arts may be directly useful in the stricter sense, but this is not the application which best displays their nature and value. The essence of the fine arts, in short, begins where utility in its narrower acceptation ends. That this principle exists in nature we immediately feel in calling to mind the merely beautiful appearances of the visible world, and particularly the colours of flowers. The fine arts in general may be considered the human reproduction of this principle. The question of their utility therefore resolves itself into the inquiry as to the intention of the beauties of nature.

With regard to the classification of the arts, those are generally considered the most worthy in which the mental labour employed and the mental pleasure produced are greatest, and in which the manual labour, or labour of whatever kind, is least apparent. This test would justly place poetry first. It would be an invidious as well as a very difficult task to assign the precise order in which painting, sculpture, architecture and music, would follow poetry and its sister, eloquence; but it may be remarked, that the union of the arts is a hazardous experiment, and is often destructive of their effect.

ARTS, MANUFACTURING. As the fine arts are destined to the production of objects beautiful rather than useful; so do the manufacturing arts produce results useful rather than beautiful. But in all the better epochs of society, these two divisions have tended to coalesce into one: the useful and the beautiful, the *utile et dulce*, being found reciprocally to lend strength to each other. The union of Science and Arts, too, is becoming more and more apparent. It has been remarked by a writer in the 'Edinburgh Review,' (vol. 78) that 'Art will not sufficiently develope her powers, nor science attain her most commanding position, till the practical knowledge of the one is taken in return for the sound deductions of the other. Many causes have concurred to place art and science at variance; but these causes have been gradually diminishing; and in the present advanced state of mechanical and useful arts they have almost wholly disappeared.'

The establishment of Art-Manufactures, in which sculptors and painters of eminence are employed to design models and patterns for manufacturers; the formation of Schools of Design, where drawing and modelling, with an especial relation to manufactures, are taught; the still more recent establishment of artizan schools, where similar instruction is given under different arrangements—all point to a union between fine art and manufacturing art; while Mechanics' Institutions, Lyceums, popular Treatises on Science—so far as they have realised the anticipations concerning them—point to a union between Science and Manufactures. Again, such discoveries as those relating to Photography, Electrography, &c., point to a union between science and fine art. Thus do all three—Science, Art, and Industry—stand in intimate relation one to another. [DESIGN, SCHOOLS OF; MANUFACTURES.]

ARUNDEL MARBLES, are certain pieces of sculpture, consisting of ancient statues, busts, mutilated figures, altars, inscriptions, &c., the remains of a more extensive collection, formed in the early part of the seventeenth century by Thomas Howard, Earl of Arundel, and presented in 1667 to the University of Oxford, by his grandson. The earl collected these fine specimens during a residence in Italy about 1613.

We learn from catalogues, that the Arundelian collection, when entire, contained 37 statues, 128 busts, and 250 inscribed marbles, exclusive of sarcophagi, altars, fragments, and the inestimable gems.

Arundel House and gardens were converted into streets about the year 1678, when it was determined to dispose of the statues by sale. One portion, consisting principally of busts, was purchased by Lord Pembroke; these are now at Wilton. A second was purchased by Sir William Fermor (the father of the first Earl of Pomfret,) who removed them to his seat at Easton Neston in Northamptonshire. Henrietta Louisa, countess dowager of Pomfret, in 1755, transferred these marbles to the University of Oxford, where they became again united to the inscribed marbles which had descended to Henry, second son of the former and sixth Duke of Norfolk, and had been presented by him to the University, in 1667. A few statues and broken fragments were given to a Mr. Arundel, a relation of the Duke of Norfolk; one or two of these were subsequently given to the Earl of Burlington, and went to Chiswick House. A few elegant remains were carried to Mrs. Temple's seat at Moor Park, near Farnham, in Surrey. The cameos and intaglios finally became the property of the Dukes of Marlborough; and are now known by the name of the Marlborough Gems.

The greater part of the Greek inscriptions in the Arundel collection now at Oxford were obtained at Smyrna. They arrived in England in 1627, soon after which they were carefully examined by the learned Selden, who in 1628 published his 'Marmora Arundelliana,' a thin quarto volume, in which twenty-nine Greek and ten Latin inscriptions of this collection are deciphered and illustrated.

The Arundel and Pomfret marbles are at present preserved at Oxford in two rooms belonging to the public schools, beneath the picture gallery. Of the Arundel portion, that which the University places at the head of its collection is the Greek inscription known by the name of the *Parian Chronicle*. Among the more important marbles of the Pomfret donation are the colossal torso (for that portion only is antique) of a Minerva Galeata, restored as a statue by Guelfi; a Venus Vestita, or Leda; Terpsichore; a young Hercules; an Athleta, which has been called Antinous; a female figure, unrestored, of early Greek work; and three statues of senators, one of which is usually considered as Cicero.

AS. The Roman As was a weight, consisting of twelve *unciæ* or ounces; it was also called *libra*, *libella*, and *pondo*, or the pound.

As, assis, or *Assarius* was likewise the name of a Roman coin of copper, or rather of mixed metal, which varied both in weight and composition at different periods of the commonwealth; but which originally actually weighed a pound, whence it was called *As libralis*, and sometimes also *Æs grave*. The earliest Ases were cast probably in imitation of the Etruscan coins, which the Romans appear to have copied. In the British Museum there are even four Ases united together, as they were taken from the mould or matrix, in which many were cast at once. In most of the Ases preserved in our cabinets, the edge shows evidently where they were severed from each other, and where the piece at the mouth of the mould was cut off. From being cast, it will be judged that they are not very correctly sized. As the As fell in weight, the smaller divisions were not cast, but struck.

The coined divisions of the As were numerous, including halves, thirds, fourths, fifths, sixths, twelfths, &c. There were also larger coins, representing various multiples of the As.

ASAM or ASSAM, is chiefly interesting in a commercial point of view for the attempts there made to cultivate the tea-plant. This wild country lies north-eastward of Hindustan, and is to a certain extent dependent on the East India Company. Reports having reached the Calcutta Government, relating to the value of the tea-plant found in Asam, a scientific deputation was despatched thither about the year 1836, to enquire into the subject. Tea-plantations were subsequently established, under the management of Mr. Bruce, who examined the surface of the country with a view to select spots favourable to the culture. Chinese labourers were engaged; and small portions of Asam tea have since been annually produced. An Asam Tea Company has been formed, and the tea sent to market is found to possess the customary qualities of Chinese tea. The Asam Tea Company established a steamer on the Brahmapootra, from Calcutta to Asam; and they imported Coolies from the interior of India at vast expense, as labourers; but it has been found that a more cautious expenditure of capital is necessary to the success of the infant enterprise. The tea-plantations are placed in some jeopardy by the hostility of the native Asamese to these new industrial arrangements. [Tea.]

ASBESTUS must be considered in mineralogy, rather as a term implying a peculiar form sometimes assumed by several minerals, than as a name denoting a particular species; it is in fact applied to varieties of the amphibolic minerals, such as actinolite, tremolite, &c., which occur in long capillary crystals, placed side by side in parallel position, and thus giving rise to a fibrous mass. Those varieties, the fibres of which are very delicate and regularly arranged, are called *amianthus*, a Greek term signifying unpolluted, unstained. Of the finest kinds, the individual crystals are readily separated from each other, are very flexible and elastic, and have a white or greenish colour with a fine silky lustre. Though a single fibre is readily fused into a white enamel, in mass it is capable of resisting the ordinary flame, so that when woven it produces a fire-proof cloth. Those varieties in which the crystals are coarser, with scarcely any flexibility, are called common asbestus. It is generally of a dull green, and sometimes a pearly lustre, and readily fuses before the blow-pipe flame. It occurs more frequently than the amianthus, or finer kind, and is usually found in veins traversing serpentine.

There are three other varieties known by the names of mountain feather, mountain wood, and mountain cork, which differ from the common asbestus by the fibres interlacing each other.

In 1845 Mr. Penny of Glasgow described a peculiar substance which had nearly all the characters of asbestus. It was found in a blast furnace, imbedded in the mass of matter which had collected at the bottom of the furnace in the course of two years and a half, and which is technically called the *hearth*. It was in a cavity, about eight inches below the level on which the liquid metal rested. This substance is colourless, inodorous, and tasteless; and occurs in small masses, composed of extremely minute filaments, cohering longitudinally together; these fibres are very easily detached, and are flexible, though not so much so as those of common asbestus; they have a silky lustre, and are unattacked by the common acids; they remain unchanged in the flame of a spirit lamp, and are difficult of fusion even with the blow pipe. This substance consists chiefly of silica, protoxide of manganese, and alumina; it differs from common asbestus chiefly in having about ten per cent. more of silica, and in containing manganese instead of magnesia. Mr. Penny thinks that the occurrence of this substance in an iron furnace furnishes a proof of the igneous origin of asbestus.

Many remarkable proofs have been given, of the power of asbestus to resist heat. Chevalier Aldini about twenty years ago had some asbestus woven into cloth, and the cloth made into garments; he clothed himself in these garments, and exhibited sundry astonishing feats before the Royal Society, such as holding red-hot iron in a gloved hand, &c. This material has sometimes been proposed for firemen's dresses, and for garments calculated to resist heat generally.

ASH. The ash is one of the most useful of our British trees, on account of the excellence of its hard tough wood and the rapidity of its growth. In its appearance too it is singularly graceful for a European tree, often resembling in its slender stems and thin airy foliage the acacias of tropical regions. The principal objection to the ash is the injury it does to the plants which grow in its neighbourhood, by rapidly exhausting the soil of all its organizable materials.

The principal varieties of the ash are:—1, the *Weeping Ash*, with all the characters of the common wild tree, except that the branches grow downwards instead of upwards, so that, if grafted upon a lofty stem, the head will soon reach the ground and form a natural arbour. This is said to have originated accidentally in a field at Gamlingay, in Cambridgeshire; 2, the *Entire-Leaved Ash;* 3, the *Curled-Leaved Ash*, with very short stunted branches, and deep green crumpled leaves; 4, the *Warted Ash.* In this the stems are covered over with a great number of little grayish brown tubercles. 5. The *Small-Leaved Ash.* 6. The *Flowering* or *Common Manna Ash*, whence the manna of the shops is procured.

The uses of the ash in the arts are very numerous. The wood is both elastic and tough. It is used for the felloes and spokes of wheels, the beams of ploughs, the tops of kitchen tables, milk-pails, oars, blocks and pulleys, handles for spades and other implements, hop-poles, hoops, crates, basket handles, fence-wattles, and numerous other purposes. In the neighbourhood of the Staffordshire potteries the ash is cultivated to a great extent, and cut every five or six years for crate-wood, which is in much demand in the pottery district. The ashes yield good potash; the bark is used for tanning nets and calf-skins; the leaves and shoots are used for food by cattle, and the dishonest use ash-leaves for adulterating tea; the seeds or *keys* are sometimes pickled as a sort of salad, and they are used in Siberia to give a flavour to water for drinking. The sap is used for some medicinal purposes. The *Flowering Ash*, as before stated, yields a juice which solidifies into manna.

The Mountain Ash is wrongly named; it belongs to another genus of plants.

ASHANTEES. How far distant the time may be when this West African nation will be commercially important, will depend chiefly on the energy of English merchants, and on the lessening of the slave-trade.

The principal manufacture of the Ashantees is that of cotton cloth, which they weave on a loom worked by strings held between the toes, in webs of never more than four inches broad. Silk is sometimes interwoven with the cotton. The cloths which they produce are often of great fineness of texture, and their colouring of the highest brilliancy. They paint their patterns with a fowl's feather. Another of the arts in which they have attained considerable excellence, is the manufacture of earthenware. They also tan leather, and work in iron, brass, and gold. Articles formed of gold abound in the houses of all the wealthier inhabitants; and in the king's palace those of most common use are described as being made of this precious material.

Gold is found in this country both in mines and in particles washed down by the rains. According to Dupuis, the richest gold mines known to exist in any part of Africa are those in Gaman. Some of the richest of these mines are said to be esteemed sacred, and on that account are not worked. The wealthier inhabitants load their persons with lumps of native gold; some which Dupuis saw, he thinks, must have weighed fully four pounds. In Akim, and some other parts of the empire bordering on the Volta, from which much gold was formerly obtained, the mines are now either exhausted, or at least are no longer worked. There are many rich mines in the small district of Adoom, westward from Cape Coast and about three days' journey from the sea; and during the rainy season it is said that not fewer than eight or ten thousand slaves are employed in washing for gold dust on the banks of the Bara, in Gaman.

ASH-BALLS. As a cheap substitute for soap, in various processes of washing and cleansing, the ashes of various kinds of plants, especially ferns, are damped and made into lumps, which are known by the name of *ash-balls.*

ASHES, the remains of anything burned, whether of vegetable or animal origin, and to a certain extent of mineral bodies also.

Vegetable ashes. Ashes vary in composition according to the nature of the plant, the soil in which it grows, and the manure used upon it. The substances usually contained in the ashes of land plants are potash, soda, lime, magnesia, silica, the oxides of iron and of manganese, chlorine, carbonic acid, sulphuric acid, and phosphoric acid. Alumina occurs rarely, and sometimes oxide of copper has been met with. Very frequently more than one half of the ashes of vegetables consists of carbonate of lime. The quantity of ashes varies, not only according to the soil, age, and aspect of the plant, but also in different parts of the same plant, from 2 to 6 per cent. of its weight, after drying in the air. The soluble part of wood ashes consists of the alkaline sulphates, carbonates, and chlorides; while the insoluble matter is chiefly composed of carbonate of lime, and probably of magnesia, phosphate of lime, and phosphate of iron.

The incineration of wood is a most important operation; from its ashes are obtained the immense quantities of impure potash, and the carbonate called *pearlash*, imported from America and other countries. The sap of plants contains also other vegetable acids, as the oxalic, citric, tartaric, malic, &c.; and the salts which these form with potash are decomposed by heat, and yield the carbonate. The ashes of land plants yield principally the salts of potash, such as *barilla*—those of marine plants afford a large quantity of soda salts, and especially the carbonate, such as *kelp*.

Coal ashes are extremely various both in their appearance and composition. Thus, much of the coal of the north of England, under common circumstances, burns to a cinder, which is a mixture of the ashes of the coal with some carbonaceous matter requiring rather a high temperature to burn it, on account of its being enveloped by incombustible matter. The coal of Somersetshire burns to red ashes, evidently coloured by peroxide of iron: those of the Staffordshire coal are nearly white. The quantity of ashes yielded by different kinds of coal varies considerably; according to Kirwan, Wigan coal contains 1·57 per cent. of ashes; Whitehaven coal 1·7, and Swansea coal 3·33 per cent.; they consist principally of silica and alumina, with small quantities of lime, sometimes magnesia, and also peroxide of iron; but they do not contain either the chlorides, phosphates, or alkaline salts found in wood-ashes. *Peat ashes* differ chemically from both the other kinds.

Animal ashes resulting from the burning of bones and other animal solids, consist principally of phosphate of lime, with traces of salts of lime, magnesia, and soda.

Mineral ashes, such as those of Vesuvius, as examined by Vauquelin, were grayish in colour; they were tasteless, and found to consist of alumina, oxide of iron, muriate of ammonia, sulphate of lime, potash, copper, manganese, lime, and charcoal. Vauquelin also analyzed the ashes ejected in the same year from Ætna; they were of a gray colour, and in fine powder; they contained sulphur, sulphates of lime, copper, and alumina, and several other mineral ingredients.

The *ashes* of domestic economy, comprising not only the coal-ash from the grate, but a quantity of dust and miscellaneous fragments, are a valuable commercial article. The ash-heap of a dust contractor has a large money-value, for much of the waste serves as material for manufactures.

ASHFORD, Kent, is one of those towns which, originally only a centre for an agricultural district, has been converted by railway enterprise into an important scene of manufacturing and trading industry. Ashford has been made a first class station for the South Eastern Railway, and the place of junction with the branch lines to Hastings and Ramsgate. The railway company owing to its convenient position have erected near the station a new village, comprising a factory for the repair of their locomotive engines, and extensive buildings for making and storing their carriages, together with about 200 dwellings (completed and in course of erection) for their workmen.

ASHLAR, or ASHLER, is a term applied in masonry to rough stones as they are taken from the quarry, and also to the dressed stones used for the facing of walls, which may be either plain, tooled, or rusticated. The word is spelt both ways; but Nicholson, in his 'Architectural Dictionary,' gives *ashlaring* as the term for the operation of bedding such slabs of stone as are employed for facing brick or rubble walls; and *ashlering* as a term in carpentry for the short pieces of upright quartering used in garrets to cut off the acute angle between the floor and the sloping rafters of the roof.

ASHOVER, in Derbyshire, has somewhat fallen away from its former rank in respect to manufactures. Formerly there were in the parish considerable lead-mines, but they have long ceased to be worked. Limestone is quarried to some extent. Medicinal herbs are cultivated in considerable quantities. There is a twisting mill for the Nottingham lace manufacture. Stocking-weaving, once an important branch of industry, is on the decline, and tambour working has ceased.

ASHTON-UNDER-LINE is one of the busiest of the Lancashire cotton-towns. It has a population of about 25,000 in the town, and 50,000 in the parish. The following details respecting the Ashton cotton mills are taken from a parliamentary paper; they refer to the year 1843, first in respect to Ashton alone, and then to Ashton together with the surrounding neighbourhood of Staleybridge, Dukinfield, Hyde, and Mossley.

	Ashton alone.	Ashton with Staleybridge, &c.
Mule spindles	595,276	1,866,062
Throstle spindles	9,000	33,136
Power looms	6,738	22,706
Steam engine horse power	1,667	5,353
Hands employed	10,520	34,165
Weekly wages	£5,775	£18,763
Weekly consumption of cotton	338,390lb.	1,063,515lb.

Staleybridge nearly equals Ashton in these particulars. Bleaching, dyeing, and calico printing are also carried on. Hats, woollens, and silks are manufactured. There are more than 20 collieries in the immediate vicinity, which employ upwards of 1000 hands. Ashton is connected with various districts by the Ashton and Manchester, the Ashton and Huddersfield, and the Peak Forest canals; also by the Sheffield and Manchester, the Lancashire and Yorkshire, and other railways.

The manufacturers of Ashton are preparing for the Exhibition of 1851, in those departments of industry for which it has become noted; and the operatives there, as elsewhere, have commenced those joint-stock arrangements which will enable them to visit the metropolis during that busy year.

ASIA. To trace the steps by which commercial enterprise has successively discovered the various parts of the Asiatic continent, would be little less than to trace the history of the human race; for, from the time when the Phœnician merchants spread their trading ports far and wide, to the day when the ports of China were laid open to British shipping and manufactures, there has been a continued series of discoveries, which have had commerce and manufactures among their moving impulses.

Nor would it be easy to enumerate the natural productions which Asia affords to the manufacturer and the merchant. Extending as it does from the burning sands of Arabia to the icy shores of Siberia, from the level plains of Tartary to the lofty heights of the Himalaya, it presents a countless variety of mineral, vegetable, and animal products. The fur-bearing and wool-bearing animals, and those numerous animals which yield flesh for food, milk for drink, and skins for leather, are found in great variety and number. Timber trees, plants used in various arts, and plants used for food, are also bountifully supplied. We need only proceed to any details in noticing the chief *mineral* products.

Among the mineral products of Asia, precious stones are very abundant. Rock-crystal is found in the greatest variety; amethysts in the Altai, Himalaya, and Ural Mountains; carnelians and agates, in western India and in the Gobi desert; casholongs and onyxes, in Mongolia; yu, or oriental jade, in Turkistan; different kinds of jasper, in the Altai mountains; pearl-stone, marcasit, on the shores of the Gulf of Okhotzk; beryl, in the mountains near the Lake of Baikal; lapis lazuli, in the same mountains, as well as in the Hindu Coosh, and on the banks of the Oxus; topazes, in the Ural Mountains; circony, chrysoberyl, sapphires, on the island of Ceylon; rubies, in Ceylon and in Badakshan; turquòises, in Khorasan; diamonds in Deccan, Borneo, and the Ural Mountains.

Volcanic products are met with on the Sunda Islands, in Japan, and Kamtchatka, in the neighbourhood of Tauris, and many parts of the high-land of Armenia, and in Western Anatolia.

Steatite, earth-flax, asbestus, and kaolin, or the finest porcelain-clay, are found in China and Japan; talc in Siberia; coals in northern China, and different parts of Hindustan; rock-salt in the Ural Mountains, northern China, the Panjab, Ajmeer, Yemen, Anatolia; salt in the salt-seas of the steppes, and sometimes on the surface of the ground; sal-ammoniac in the volcanic steppes of Central Asia, not far from the river Ili; nitre in Hindustan; borax, or tinqual, in Tibet; petroleum, near Baku, on the shores of the Caspian Sea, on the Euphrates at Hit, and other places, and at Kerkook east of the Tigris; asphaltum on the Dead Sea, in Palestine. Hot springs are very abundant in the snow-covered mountains of the Himalaya range, especially along the upper branches of the Ganges, and also in the N. W. of Anatolia.

Of the metals, gold is found in Japan, Tibet, Yun-nan, Cochin China, Tonkin, Siam, Malacca, Borneo, Asam, Ava, and in the Ural Mountains; many rivers bring down gold in their sands; silver in China, Da-uria, Japan, Armenia, Anatolia, and the Ural Mountains; tin in Malacca, Anam, the Sunda Islands, and the empire of the Birmans; mercury in China, Japan, and Tibet; copper in the Ural and Altai mountains, Japan, China, Nepaul, Azerbijan, Armenia, and Mount Taurus; malachite in China and Siberia; iron from the Ural Mountains, through central Asia as far as the Peninsula beyond the Ganges, as well as in Japan and Persia; lead in Da-uria, China, Siam, Japan, Georgia, and Armenia.

Under the names of the principal countries in Asia, the reader will meet with some further information on the industrial resources of the East.

ASIA MINOR. This rich, outlying portion of Asia, often designated *Natolia* or *Anatolia* by geographers, contains many mines; but the mining operations are not conducted with much skill. There are copper mines near Bákír-Kurehsí, not far from the Black Sea; near Chalwár, on the eastern side of the Lazian group; near Tireból i, on the Black Sea; near Tókat, and many other places. There are iron mines near Unieh, on the Black Sea; silver with copper, in the mines of Tireból i; silver and lead at Denek, in the Begrek-Dágh, east of the Kizil-Irmák. Nitre is got at Kará Búnár, in the south-eastern part of the central table-land. Rock salt abounds in all parts, especially in the north-eastern part of Asia Minor and in the tract round Angora. Hot springs occur in all the provinces; those of Brúsá are celebrated, and are even visited by European patients.

The northern shores of Asia Minor are covered with magnificent forest trees of various kinds. The forests, stretching west from Boli, the great and almost inexhaustible source of supply to the Turkish navy, contain ash, elm, plane, poplar, larch, and beech, and some oaks of large size. It is known to the Turks by the significant name of *Agatch Degnis*, or Sea of Trees. The mountains of Karamania are in general well wooded, and Alexandria is mainly supplied with fuel from them. The timber of this coast, at least that near the shore, is chiefly pine, but not in general of large dimensions. The mountains of Taurus contain a great variety of forest trees and shrubs.

No road, in the European acceptation of the term, has ever existed of their own construction in the empire of the Turks. Asia Minor still presents remains of the Roman lines of communication; and of the Roman bridges many yet are in use. Relays of post-horses are still maintained by the Turks at distant intervals. They are principally stationed at the large towns of the leading routes. The most frequented road is that from Smyrna to Constantinople, and the only one by which there is a regular communication, except by caravans. Important as is the trade between these great cities and the rest of Europe, this correspondence takes place but twice a month, and is managed by the Austrian mission and consulate, which, as well as the Russian, despatch, at stated periods, a post to the European capitals. The Porte keeps in constant employment a corps of Tatar couriers, by means of whom they make all their communications. On a smaller scale every pasha has a similar establishment. The route from Smyrna to Constantinople passes by way of Magnesia, Thyatíra, and Moukalitsch. Another route extends from Constantinople to the southern Pashaliks. It goes by way of Mudanieh, Brusa, the Olympus range, Kutaya, Afium-Kara-Hissar, Konieh, Káráman, and Gulnar. A third route advancing in the same direction from the Bosporus, at Eski-shehr pursues an exact eastern course, and reaches Angóra, whence two routes branch off.

ASPA'RAGIN, a peculiar substance obtained from asparagus, and also from marsh-mallow root; it is also contained in the potato, liquorice-root, and beet-root. It crystallizes in transparent limpid colourless prisms. It is inodorous, has a mawkish disagreeable taste, and is rather hard.

ASPA'RAGUS. The common cultivated asparagus is found in sandy and maritime places in most parts of the middle and south of Europe, the Crimea, and also of Siberia and Japan. Attention being paid to the preparation of the soil, asparagus is one of the easiest of all vegetables to cultivate; but no art or skill will produce precisely the soil which is most favourable for its growth. This exists naturally in some places in the fittest of all possible states, and it is there only that it is to be obtained in its greatest perfection; as in the rich alluvial soil of Battersea, Mortlake, and other places round London: in some of these villages it is produced of such extraordinary size that 110 heads in a state fit for the kitchen have been known to weigh more than 32 lbs.

In this country asparagus is frequently forced, but seldom with much success. In many parts of Europe, however, especially about Riga, a mode of forcing is adopted which causes the asparagus to be much finer than any obtained in this country by artificial means.

ASPERGILLUS is the blue mould or fungus which appears on cheese, lard, bread, &c. Its colour is sometimes imitated by fraudulent dealers by sticking brass pins into the cheese—the verdigris formed from the pins giving the desired colour.

ASPHALTE is a name given to various bituminous compounds, which have been much used of late for street-pavements, for the platforms of railway stations, and for flooring, roofing, and protecting buildings in various ways from damp. One of the most important of these is the Seyssel asphalte, introduced into this country by Mr. Claridge, under a patent obtained in 1837.

The principal ingredient of the asphaltic mastic of Seyssel is a dark brown bituminous limestone, found near the Jura Mountains. This stone is broken to powder and mixed with mineral tar, when intended for fine work, such as the covering of roofs and arches, the lining of tanks, and application as cement; or, when intended for the coarser purposes of pavement and flooring, with mineral tar and sea-grit; and the whole is exposed for several hours to a strong heat, in large caldrons, until the ingredients, which are continually stirred by machinery, are perfectly united. The mastic is then run into moulds so as to form it into large cakes or blocks, which are broken up and re-melted on the spot in portable caldrons, with wood or coke fires, with the addition of a little more mineral tar; the whole being well stirred to prevent burning, and to ensure the perfect mixture of the ingredients. When ready for use the mastic emits jets of light smoke, and drops freely from the stirring instrument. It should then be carried very quickly to the spot where it is to be applied, in iron ladles or heated iron buckets. In all cases, however, it is desirable to have the caldron as close to the work as possible; and in covering brick arches or arched roofs, it may be hoisted to the top of the building, proper precautions being observed to shelter the finished work from injury.

Pavements of asphalte are laid upon a firm and dry foundation of concrete; and in laying the asphalte the surface is divided by slips of wood, which serve as gauges to regulate the thickness, into compartments of about thirty inches wide, in which the hot cement is spread and levelled with wooden instruments; after which, while the surface is yet soft, sand mixed with slate-dust, dead plaster of Paris, or powdered chalk, or, for coarser work, clean sharp grit is sifted over it, and rubbed or beaten in. The thickness of asphalte used for pavements varies from half an inch to about an inch and a quarter; from half an inch to five-eighths is sufficient for roofs and the covering of arches to prevent the filtration of water, and for the lining of tanks and ponds; and about half that thickness is sufficient for covering the ground-line of brickwork, to prevent the rising of damp.

The experience of the last few years has shown that asphalte is neither a pleasant nor a profitable material for the pavements of the London streets.

ASPHALTUM is one of the varieties of bitumen, arising from the decomposition of vegetable matter. [BITUMEN.] It occurs massive, of a dark brown or black colour, with a conchoidal fracture, and a resinous lustre. It is opaque, and exceedingly brittle at a low temperature, but softens and fuses by the application of heat. It is insoluble in alcohol, but soluble in about five times its weight of naptha, with which it forms a good and useful varnish. Its combustion is rapid and brilliant, with the production of the bituminous odour.

It is found in many countries, but most abundantly on the shores, or floating on the surface of the Dead Sea; at Hit, above Babylon, on the Euphrates; and near the Tigris. In Trinidad in the West Indies it fills a basin of three miles in circumference and of unknown depth. The Earl of Dundonald has recently (1849) made some experiments on the availability of the Barbadoes asphaltum for fuel; he mixed it with coal (two parts of asphaltum to one of coals) and found that it made a good fuel for steamers; he also devised a form of furnace for burning it. There is a pitch-spring in Zante, which is known to have been at work for above 2000 years. Asphaltum is the principal colouring matter of the dark indurated marl, or shale, which is found in coal districts.

A liquid asphaltum, useful as a black japan or varnish, is made by melting asphaltum with Scio turpentine and oil of turpentine; or substituting balsam of copaiba for the Scio turpentine.

Counterfeit asphaltum is occasionally substituted for the real; it consists of the dregs of Barbadoes tar, heated until quite hard.

ASS. This ill-used and ill-appreciated animal (in England, at least) takes an important part in oriental travelling and commerce. The fine Arabian asses are used only for the saddle, and are imported in great numbers into Persia, where, according to Chardin, they are frequently sold for 400 livres; they are taught a kind of easy ambling pace, are richly caparisoned, and used only by the rich and luxurious nobles. A fine breed, of Arab lineage, used exclusively for the saddle, exists in Syria; —a small spirited and graceful kind is also found in Syria, upon which the ladies ride from preference; and besides this there is a stout breed fitted for ordinary labour. Another breed, that of Damascus, is characterized by the length of its body and of its ears; it is much employed by the bakers of Damascus in carrying flour and brushwood. The ordinary asses of Persia are strong, but in other respects not to be compared to those of Arabia. As we proceed farther eastward the ass degenerates, and in India it is very small, of inferior qualities, and used only by the people of the lowest caste. The finest asses of Europe are those of Malta and Spain. Italy also possesses a superior breed; and the same remark applies to some parts of France, as Le Poitou and Le Mirebalais.

It is a curious example of the extent to which nature is imitated by man, either for honest or dishonest purposes, that artificial *asses' milk* is manufactured. One recipe comprises new cow's milk, sugar-candy, ground rice, and eringo root; while another comprises water, hartshorn shavings, lump sugar, new milk, and syrup of tolu.

ASSAFŒTIDA is a gum-resin, obtained from the roots of the *Ferula assafœtida*, a perennial plant growing in Persia, in the province of Lar, and in Khorassan. In its recent and purest state it is white and transparent, but by exposure to the air it becomes of a clear brown colour, sometimes verging to red or violet, and of a waxy appearance. The inferior sort is dark-brown, of a dull fatty appearance, viscid, and greasy; it is called assafœtida in masses. The smell of assafœtida is penetrating, very disagreeable, and lasts some time. The taste is bitter, unpleasantly aromatic, of an alliaceous or garlic-like character.

Assafœtida acts on the human system as a stimulant, and is employed in various ways in medicine.

ASSAYING. The difference between assaying and chemical analysis may be thus stated; that when an analysis is performed, the nature and proportions of all the ingredients of a substance are determined; but in assaying, the quantity of any particular metal only which the ore or mixture under examination may contain is ascertained, without rereference to the substances with which it is mixed or alloyed. Assaying is sometimes conducted in what is called the *dry way*, or by heat; at other times in the *moist way*, or by acids and other re-agents; and in some cases both methods are necessarily resorted to in assaying the same ore or mixture of metals.

The assaying of silver and gold is effected by a process called *cupellation*. Cupels are small flat crucibles made by pressing bone ash, moistened with water, into circular steel moulds, and they are dried by exposure to the air. The principle upon which the operation depends is, that all metals with which gold and silver are usually alloyed, are convertible into oxides by exposure to atmospheric air at a high temperature, whereas the precious metals remain unacted upon.

To assay *silver* by cupellation, the silver is flattened, and wrapped up in an envelope of lead. A muffle or oven is heated in an assay furnace, and the two metals put into it. The metals melt, and the lead becomes converted into an oxide, which, as well as any baser metals before combined with the silver, is absorbed by the substance of the cupel, until at length the silver is left absolutely pure.

The assaying of *gold* is performed, to a certain extent, exactly in the same way as that of silver; and if the gold were alloyed only with copper, the process would be as simple as that of silver assaying. Usually, however, gold contains silver, and this cannot be got rid of by cupellation, the *parting* process is therefore had recourse to; this consists in dissolving the silver by dilute nitric acid, which leaves the gold perfectly pure.

Iron ores are assayed by separating the oxygen from the iron, by the greater affinity of charcoal for that element at high temperatures. The ore, some charcoal, and an alkaline flux, are heated in a crucible; and the result is that all the impurities in the ore are made to leave the iron, so that the latter is presented in a purely metallic form.

Copper ores for the most part contain sulphur; and in order to assay them, a flux is prepared of fluor spar, borax, slaked lime, argol, and nitre. The ore is pounded, calcined in a crucible at a red heat; then cooled; then heated again with some of the flux until it is brought to a liquid state. The liquid metal is poured into a mould, and quenched when solid but yet hot. There is then found a portion of metal underneath a layer of coarse slag. The metal is separated from the slag, reduced to powder, and again heated until the sulphur is driven off from it.

Lead.—The principal ore of lead is the sulphuret, commonly called galena; but the carbonate, or white lead ore, is sometimes found in considerable quantity. The former of these is assayed by being put into a crucible with iron and flux, all in small grains; and after being covered with a layer of salt, they are heated until the lead becomes separated from all impurities. The second kind of ore is assayed in the same way, but with a different flux.

Tin.—The ores of tin are principally of two kinds, the oxide and the sulphuret. The oxide is assayed by simple fusion with a flux, which removes the oxygen. The sulphuret is assayed by being first pounded and calcined, to drive off any sulphur or arsenic; and then melted again with a flux of alkalies, fluor spar, and lime, by which the tin becomes separated from all the other impurities.

Zinc.—The ores of zinc are of two kinds, the carbonate, or calamine, and the sulphuret or blende. The carbonate is assayed by being broken into small pieces, brought to a red heat, cooled, reduced to a fine powder, mixed with powdered charcoal, and melted in a crucible, under such conditions that the zinc may leave the ore, and combine with a thin layer of granulated copper so as to produce *brass;* and the quantity of the brass so produced tests the richness of the ore in zinc. The sulphuret, or blende, is assayed nearly in the same way.

ASSIGNAT. The commercial history of an assignat bears some such relation to that of a bank note, as a swindler does to an honest trader. During the early stages of the French Revolution, the government siezed the clergy lands, and made them over to the municipalities; the municipalities gave security for the value, which securities the government ordered should be a legal tender. Paper money was issued to represent these securities; and the paper notes were called *assignats*, or tokens that church-land had been *assigned* to the holder. The government once having began this system, were induced to proceed; and issued more and more assignats, though there was nothing to be represented by them. By the end of 1792 the assignats had been issued to the extent of nearly 3000 million francs; and as they were not convertible into cash, one silver franc became after a time worth two paper or assignat-francs, then three, then six. During a flash of national glory, in 1793, the assignats rose for a brief period to par, but speedily fell again. By 1794 the number had increased to 6,500 millions, and in the next year it increased to 19,000 millions, the market value being less than one-hundredth of the nominal value. In 1796 the sum reached 36,000 million francs; but the scraps of paper were almost entirely worthless; and as the government officials at length refused them in payment of salaries, the whole thing fell to the ground.

The misery which this nefarious system inflicted is incalculable. There are at the present time, in France and Belgium, rooms which have been completely papered with assignats —for all of which money or money's value had been given, but which became utterly worthless.

ASSIZE. In early times there were assizes or ordinances regulating the price of bread, ale, fuel, and other common necessaries of life, called in Latin *assisæ venalium*. The earliest express notice of any regulation of this kind in England is in the reign of King John (1203), when a proclamation was made throughout the kingdom enforcing the observance of the legal assize of bread: many statutes were passed regulating the assize of articles of common consumption; the earliest of these is the assize of bread and ale, 'assisa panis et cervisiæ,' commonly called the stat. of 51 Henry III., though its precise date is doubtful. The stat. 8 Anne, c. 19, repealed the 51 Henry III., and imposed a new assize of bread, and made various other regulations respecting it. Several subsequent acts have been passed on the subject; but by the 55 George III., c. 99, the practice was expressly abolished in London and its neighbourhood, and in other places it has fallen into disuse. Trade is now allowed to settle its own prices.

ASSURANCE. [INSURANCE.]

ASSY'RIA. We refer to BABYLON and NINEVEH for a few notices of the extraordinary works of art found in Assyria and Mesopotamia.

A'STACUS. [LOBSTER.]

ASTI. This province of Piedmont is well adapted for the cultivation of the vine. A sparkling fine-flavoured white wine, called *vino d'Asti*, resembling champagne, is made in the neighbourhood of Villanuova. The soil is also fertile in corn and fruit-trees, especially mulberries, the leaves of which serve to feed the silkworms. The chief town, also called Asti, has some trade in silk and woollen fabrics, wines, and other agricultural produce.

ASTRAGAL, a moulding used in architecture, and applied principally to the upper ends of the shafts of columns and to their bases. It is also used in the entablatures of the Roman Doric, the Ionic, Corinthian, and Composite orders. The form of this moulding is semicircular, projecting from a vertical diameter. In Egyptian architecture, bands curved after the manner of astragals seem to bind the reeds of which the shaft of the column often appears to be formed. The most remarkable example of the use of the astragal in Grecian architecture is in the base employed in the Ionic temple of Minerva Polias at Priene.

ASTRA'GALUS. [TRAGACANTH GUM.]

ASTRAKHAN. This Russian province depends a good deal for its commercial prosperity on its fisheries. The Volga is scarcely equalled by any other stream in the world for abundance of fish. This noble river flows through the province. In the spring of the year its fishing-grounds, particularly between the sea and the capital, are so abundantly stocked with fish, as to employ upwards of five thousand vessels, and twice that number of persons, who are brought by the fisheries from remote places. Isinglass and caviar are brought from this region.

Goats are reared, not so much for the sake of their milk or flesh, as of their hides, with which the Russians prepare morocco-leather: there is a fine species of hair too, which either falls from the animal's back, or is combed from it, out of which a stuff of beautiful texture is occasionally woven. But the greatest resource possessed by the rural population and nomadic tribes of the province is their flocks of sheep, which are valuable both for their wool and for their fat.

To the principal branches of industry already enumerated we may add the manufacturing of magnesia, tallow, and soap, in considerable quantities, distilleries of brandy and spirits, and manufactories of leather, cotton, and silk. Astrakhan soap is in much request among the Russians on account of its firm substance and fragrant scent. The Volga, which secures a ready access to the eastern shores of the Caspian Sea, has hitherto rendered the capital of this province the principal seat of the traffic carried on between Asia and the Russian dominions.

The chief city, also called Astrakhan, has a navigable communication with St. Petersburg, from which it is upwards of 1200 miles distant. The establishments for weaving silks and cottons are nearly one hundred in number; it manufactures also considerable quantities of leather, particularly a superior description of morocco and shagreen, as well as tallow and soap. The business of buying and selling, more than one-half of which has been engrossed by the Armenians, is conducted in twenty-eight khans or bazaars, which contain 1500 stores built of stone, and 560 wooden stalls. Raw silk and silk goods, cotton and cotton-yarn, drugs, dye-stuffs, carpets, oil, rice, and other eastern productions form the chief importations: the exportations are principally woollen cloth, linens, cochineal, velvet, iron, salt, fruits, fish, wine, liquorice, soda, hides, skins, and grain.

The fisheries of the Volga centre principally a little below the city. Every weir has its group of huts, with a little church attached to it, in which from two to three score fishermen reside; they are divided into divers, catchers, salting-men, and makers of caviar and isinglass. Each little colony is provided with spacious ice-cellars, which contain compartments for storing away the fish when salted, with intervals between the compartments which are filled with ice.

ASTRINGENTS are agents which contract the fibres of the muscles and blood-vessels, and lessen the flow of fluids. Without dwelling on their medical uses, we may briefly enumerate the chief substances so employed.

Of vegetable astringents the chief are *barks*, as of oak and willow, such as that of the *quercus robur*. The best willow bark is procured from the *salix pentandra*, or sweet bay-leaved willow, though very excellent bark is yielded by the *salix Russeliana*, or Bedford willow. Roots, as of tormentil (*potentilla tormentilla*); bistort (*polygonum bistorta*); common avens (*geum urbanum*), which are British plants; and rhatany (*krameria triandra*); rhubarb (*rheum palmatum*); pomegranate (*punica granatum*), which are exotic plants; leaves of arctostaphylos (*uva ursi*), petals of the *rosa gallica*, fruits of *prunus spinosa*, or sloe-thorn (*punica granatum*), and secreted juices of many plants, as kino, from *pterocarpus Senegalensis*, and several others; and catechu, from *acacia catechu*, and galls, from *quercus infectoria*; in all of which the astringent principle is tannin, with more or less of gallic-acid; and lastly log-wood, (*hæmatoxylon Campechianum*), in which hæmatine as well as tannin possesses an astringent property. Acetic acid must also be classed among the vegetable astringents.

The mineral astringents are—diluted sulphuric acid, and salts of iron, zinc, copper, silver, and the salts of lead. Cold, in whatever way applied, is also a valuable astringent.

ASTROCA'RYUM, is the botanical name for a genus of palms. One species, the *A. murimuri*, yields a delicious fruit. Another species, *A. airi*, has very hard wood, which is much used in tropical America for bows, and similar purposes, where hardness and toughness are required. The fibres of the leaves of *A. tucuma* are much valued for fishing-nets.

ASTROLABE, among the Greeks, was a circular instrument used for observations of the stars; but in the sixteenth and seventeenth centuries it signified a projection of the sphere upon a plane, being used in the same sense as the word *Planisphere.* To this small projection, which had a graduated rim, sights were added, for the purpose of taking altitudes; and in this state it was the constant companion and badge of office of the astrologer. In later times, before the invention of Hadley's quadrant, a graduated circular rim, with sights attached, called an astrolabe, was used for taking altitudes at sea.

Improved astronomical instruments have thrown the astrolabe quite out of use.

ASTRONOMICAL INSTRUMENTS. Without entering into the scientific details of astronomy, the mechanical construction of the principal instruments employed will be found under the names of the instruments themselves.

"We are rivals with Britain," says M. Dupin, speaking of his countrymen, "in mathematical instruments, and in those of philosophy, optics, and astronomy." Let us hope that the scientific instrument makers of both countries will be worthily represented in 1851.

ASTURIAS. This portion of Spain does not hold a high rank in relation to manufactures and their materials. There are found, however, marble, stone used for grind-stones, copper, mineral amber, cinnabar, iron, zinc, lead, antimony, jet, coals and turf. The mountainous parts of the province are covered with forests of oak, beech, chestnut, and other trees.

The only manufactories of Asturias are—a royal manufactory of fire-arms at Trubia, a few others belonging to private individuals for the fabrication of copper, earthenware, and jet trinkets, some tanneries, and looms for common woollen and linen stuffs, principally for home consumption. A considerable quantity of pickled fish is sent from Asturias to Madrid.

ASTY'LAR, in architecture, signifies without columns. Thus, we speak of Astylar Italian in contradistinction from the columnar class of buildings in that style, or such as are decorated with the orders. In this country we had no examples of the *astylar* class of design, until it was introduced by Mr. Barry, in the Travellers' Clubhouse and Reform Clubhouse, London.

ASY'LUM, in its original meaning, was a place of refuge. In the present day it has the same signification as a hospital or almshouse; and some of the handsomest modern structures in this country are thus called asylums, such as the Lunatic Asylum at Hanwell, and the still larger structure at Colney Hatch.

ATACA'MA, is the slip of Bolivia which lies between the Andes and the Pacific. The surrounding mountains contain mines of gold and silver, but they are not worked, and are inhabited by numerous herds of vicuñas, which the Indians hunt, selling their skins and eating their flesh, which is tender and of excellent taste. It has been proposed to bore Artesian wells at Puerto de la Mar (the only port in Bolivia), in order to remedy the want of fresh water, which is a serious bar to the prosperity, and even to the existence of the town. The interior districts contain veins of crystal of various colours, of jasper, talc, copper, blue vitriol, and alum.

ATCHEEN, or ACHEEN, one of the many petty kingdoms in the large island of Sumatra, carries on a considerable trade with Coromandel, to which it furnishes gold-dust, raw-silk, betel-nut, pepper, sulphur, camphor, and benzoin; receiving in return cotton goods and salt. A considerable trade is also carried on between Atcheen and Singapore. Coarse manufactures of cotton, woollen, and silk are carried on by the inhabitants.

ATH, or AATH, is a flourishing manufacturing town in the Belgian province of Hainault. The manufactures are caps, hats, gloves, cotton and linen cloth, bleaching, and asbestus cloth. It carries on also some trade in grain, and in the products of the neighbouring country, among which are tobacco, poppies, and rape. The mulberry is extensively cultivated in the neighbourhood for the growth of silk.

ATHENS. As long as the memory of ancient art remains, the name of Athens will be respected as the greatest of its supporters. No other city has ever contained so many buildings and sculptures of high artistic excellence. On the hill called the Acropolis is the world renowned *Temple of the Parthenon* [PARTHENON]. Near the hill called the Areopagus is the *Temple of Theseus* [THESEIUM]. Eastward of the Theseium are the remains of the *Stoa* or *Portico of Hadrian*. South of the Stoa is the *Tower of the Winds*. In the south-east quarter of the city is the *Arch of Hadrian*; and within this are all that now remain of the magnificent temple of *Jupiter Olympus*. Not far from this temple is the beautiful *Choragic Monument of Lysicrates*, which has served as the model for the steeple of one of our London churches. The great *Dionysiac Theatre* was on the south-east side of the Acropolis; while on the south west of the Acropolis was the *Odeium* or *Musical Theatre*,—and on the west was the *Propylæa* or military approach. On or near the Acropolis, too, were the large structure or structures, the remains of which are now known as the Erechtheium.

The ELGIN and PHIGALEIAN Saloons at the British Museum are richly adorned with priceless works of sculpture brought from Athens. These are briefly noticed in other parts of this volume.

ATHERSTONE, in Warwickshire, contributes its mite towards the industry of the country. The chief manufacture is that of hats. Ribands and shalloons are also made. The Coventry Canal, which passes close by the town on the west, contributes to its trade. Among the anomalous rocks by which the coal-field is bounded on the south-east, is a peculiar quartzose sandstone, of extraordinary hardness, which is extensively quarried, and sent to a great distance for the purpose of road-making. Nearly adjacent to this is a rich bed of manganese, which at Hartshill has yielded a very profitable return, but which is now nearly exhausted. Coal is found at Baddesley Moor, in the vicinity of Atherstone.

ATHLONE, which is connected with Dublin by the newly opened Midland Great Western Railway of Ireland, had formerly a considerable trade in the manufacture of coarse hats, but it has declined. There are extensive distilleries, breweries, and tanneries here, and a brisk trade is carried on by means of the Shannon navigation and Grand and Royal Canals with Limerick and Dublin.

ATLANTES, is a term applied to figures or half figures of men used in the place of columns or pilasters, to sustain an entablature. In the temple of Jupiter Olympus, at

Agrigentum, restored by Mr. Cockerell, and described in Stuart's 'Athens,' vol. 4, Atlantes are represented standing upon a plinth placed on the entablature above the pilasters of the cella of the temple, and supporting with their heads and arms the entablature on which the beams of the roof were to have been placed. The Atlantes of this temple were twenty-five feet high, built in courses of stone, corresponding with the walls of the cella, and partly attached to it.

ATLANTIC OCEAN, as the watery expanse which separates Europe from America, is one of the most notable of commercial highways.

No first-class river flows into the Atlantic from Europe or Africa, the Rhine, the Danube, the Dnieper, and the Nile being of the second class. Of Africa, about one-half the surface is supposed to be drained by rivers which, directly or indirectly, flow into the Atlantic. But, on the American side, the Atlantic rivers are on the grandest scale; including the Amazon, the Plata, the Orinoco, the Mississippi, the St. Lawrence, and their numerous tributaries. It is calculated that the areas of country drained by rivers which flow into the Atlantic and its seas are six millions in America, six millions in Africa, three millions in Europe, and half a million in Asia.

The Gulf Stream greatly affects the navigation of the Atlantic Ocean. Vessels bound from Europe to North America avoid it as much as possible, because it would create a delay of at least a fortnight if they were to stem it. They therefore either sail to the south or to the north of it, commonly the latter, their course being accelerated as soon as they approach the continent of North America by the counter-currents which run between the Gulf Stream and the coast. The Gulf Stream is now avoided even by vessels returning from the West Indies and the Gulf of Mexico, though by following its course they arrive four or five days sooner in Europe than those which avoid it. But it has been found by experience that such vessels suffer a damage in wear and tear which is greater than can be compensated by the gain of a few days.

It is a known fact that the water of the Atlantic Ocean, in different parts, contains different quantities of salt; and that the specific gravity is less near the poles than near the equator. There is a considerable difference between the specific gravity of the water of the Baltic and Mediterranean seas and the ocean. That of the Baltic contains only one-sixth of the salt which is found dissolved in the ocean, its specific gravity being on an average not more than 1·0049. The Mediterranean Sea contains somewhat more salt than the ocean; to the east of the Straits of Gibraltar, the specific gravity of the sea-water is 1·0338; whilst between Cape St. Vincent and Cape Cantin, it was only found to be 1·0294.

The Atlantic is always busily laden with the produce which is passing from the old continent to the new, and *vice versa.* Magnificent steam ships traverse it from Glasgow, from Liverpool, from Southampton, from Bremen, from Havre, to Halifax, Boston, New York, the West Indies, and South America; while sailing ships traverse its whole length on their route to the Pacific, to the great but almost unknown Southern Ocean, to the Cape of Good Hope, to India and China, and to our Australian Colonies. In a very few weeks after this page reaches the hands of the reader, ships laden with foreign treasures—treasures of productive industry—will be ascending and crossing the Atlantic, on their way to the great Gathering of Nations in 1851.

ATLAS is the historical and geographical name of an extensive mountain-system in North Africa, which, though not inhabited by a manufacturing race, produces many substances useful in the Arts. On the low plains at the southern foot of the mountains, and within its lower ranges, the date palms cover extensive tracts; the higher lands abound in gum trees, almonds, olives, and other productions of the hotter countries; the lower tablelands produce apples, pears, cherries, walnuts, apricots, and other fruits, common to the southern countries of Europe; and, proceeding higher up the ranges, the plains are covered with pines of an immense size, with a species of oak, called the *belute,* with ferns, elms, mountain-ash, and several species of juniper. Higher up, large forests of firs form the principal vegetation.

Rich mines of different kinds exist in that lateral range which separates the province of Suse from the countries on the river Draha; it abounds especially in iron, copper, and lead. Ketewa, a district east of Tarudant, contains rich mines of lead and brimstone; and saltpetre of a superior quality abounds in the neighbourhood of Tarudant itself. Other mines of iron, copper, antimony, lead, and a little silver and gold, are met with in various parts. Salt and sulphur are also found.

ATMOMETER, an instrument employed to measure the quantity of exhalation from a humid surface in a given time. The instrument to which the name is usually applied is one invented by Professor Leslie, consisting of a very thin ball of porous earthenware, two or three inches in diameter, to which is cemented a long tube of glass, marked by a diamond with divisions, each of which is capable of containing as much liquid as would, if spread over the outer surface of the ball, cover it with a film equal in thickness to the $\frac{1}{1000}$th part of an inch. The open end of the tube is fitted with a brass cap and a leather collar; and when in use the instrument is filled with distilled or boiled water, and suspended vertically with the ball downwards, the end of the tube being perfectly closed with the cap and collar. The water then percolates through the porous ball precisely in proportion to the evaporation from its outer surface, of which its waste in the tube forms an accurate indication. The vacuous space above the water in the tube becomes, during the operation, gradually filled with air which enters through the porous ball. When the tube becomes empty, the cap is removed to refill it. This instrument is not only useful in meteorological observations, but is also capable of being applied with advantage in chemical operations, and in the application of science to agriculture.

ATMOPYRE is the name given to an ingenious contrivance, very recently introduced by Mr.D.O.Edwards. *Smoke* is only one of the evils occasioned by imperfect combustion; and Mr. Edwards's invention is intended to lessen these evils. A small cylinder or tube of pipe-clay, from two to four inches long, is perforated with holes only one-fiftieth of an inch in diameter. One end of the tube is fixed upon a gas-burner; and when the gas is turned on, it becomes mixed with atmospheric air in the cylinder. The little jets which penetrate through the minute holes are ignited, the clay cylinder becomes red-hot, and has the appearance of a solid red flame. By placing these clay cylinders within others of larger size, an intense heat may be produced; and this heat (it is proposed) may be applied to many manufacturing purposes. The gas is thoroughly consumed on account of the minuteness of the threads into which it is divided; while the perforations, acting on the principle of those in the safety-lamp, prevent the flame from reaching the interior of the cylinder.

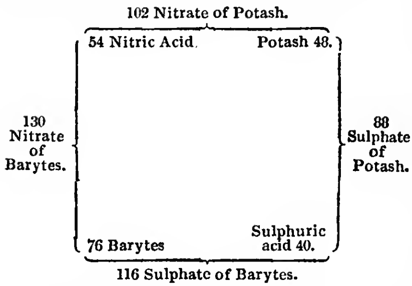
Common gas is estimated by the inventor to yield double as much heat by this method as in the ordinary mode of combustion; and this heat, by a due multiplication and combination of clay-cylinders, is proposed to be used in raising steam for warm-baths and other minor purposes, and for heating rooms. If the principle be sound, the practical applications will speedily develope themselves.

ATMOSPHERE, is the whole body of air or other mixture of gases which envelopes a planet. As we do not here treat of the atmosphere in its scientific relations, it will suffice to refer to AIR, ANEMOMETER, BALLOON, &c., where the practical results of the existence of an atmosphere are brought into prominent view.

ATOMIC THEORY, in chemistry, sometimes termed the *doctrine of definite proportions.* This very important theory, founded on well ascertained facts, has bestowed on modern chemistry an almost mathematical degree of precision. The theory, which is to be distinguished from the experimental part of the subject, supposes that chemical compounds result from the combination of the ultimate atoms of their constituent parts. It has been determined by experiment, and the fact serves as the basis of the theory, that a compound body, when pure, always contains the same proportion of its constituents: thus calcareous spar, and the pure part of marble, chalk, and limestone, consist of carbonate of lime, composed of uniform proportions of carbonic acid and lime; the carbonic acid always contains uniform quantities of carbon and oxygen, and the lime uniform proportions of calcium and oxygen. The same law also exists with regard to all similarly-constituted oxides, sulphurets, and salts, and indeed to all chemical compounds whatever, whether presented to us by nature or formed by art.

Wenzel, Bryan Higgins, Richter, Proust, and other chemists, made many discoveries which tended towards a law of definite proportions in chemistry; but Dalton reduced it to a system by his *atomic theory*, promulgated in 1803. According to his view, the *atomic number*, or *atomic weight*, or *atomic equivalent*, of any substance, represents the relative quantity or weight of each which will combine with other substances; and the labours of later chemists have been directed to the exact determination of these numbers. Dalton thought that if hydrogen were reckoned 1, all other substances might be represented by integers, and this is still frequently done; but these integers are not strictly accurate.

The following diagram will illustrate the mode in which the atomic numbers or combining weights retain their character throughout all the compositions or decompositions which may take place. An atom of nitric acid (hydrogen being taken as 1, and oxygen as 8) weighs 54; and one of barytes 76; forming when combined 130 of neutral nitrate of barytes. An atom of neutral sulphate of potash = 88, is composed of an atom of sulphuric acid = 40, and an atom of potash = 48. Now when an atom of nitrate of barytes = 130, dissolved in water, is mixed with an atom of sulphate of potash = 88, in solution, double decomposition ensues, and two new and perfectly neutral salts are formed, viz. 1 atom of nitrate of potash = 102, consisting of an atom of nitric acid = 54, and an atom of potash = 48. This remains in solution; and there is precipitated an atom of neutral sulphate of barytes = 116, composed of 1 atom of sulphuric acid = 40, and 1 atom of barytes = 76.



Tables of these combining numbers are now published for the use of chemists.

In 1809 Gay-Lussac published an important memoir on the 'Theory of Volumes,' in which the definite composition of compound gases was placed in a new and instructive light. Suspecting, from the previously ascertained fact that 100 volumes of oxygen gas combine with 200 volumes of hydrogen gas to form water, that other gaseous bodies would be found to unite in simple proportions, he made further experiments, and found that gaseous substances unite in the simple ratio of 1 to 1, 1 to 2, 1 to 3, &c. Thus, for example,—

	By Volume. Nitrog.	By Volume. Oxygen.	By Weight. Nitrog.	By Weight. Oxygen.
Nitrous oxide .	2	1 .	14	8
Nitric oxide . .	2	2 .	14	16
Hyponitrous acid	2	3 .	14	24
Nitrous acid .	2	4 .	14	32
Nitric acid . .	2	5 .	14	40

The same rule was found also to apply to the combination of vapours with gases, thus,—

Volumes.	Volumes.
100 hydrogen gas with	100 vapour of sulphur.
100 oxygen gas with	100 „
100 hydrogen gas with	100 vapour of iodine.

As Chemistry is treated in this work only in respect to some of its practical applications, this brief notice of the atomic theory will suffice.

A'TRIUM, a hall or room of audience in a Roman house. The Cavum Ædium was probably the hollow space in the middle of a Roman house, open to the sky and rain; while the Atrium was the covered part, the hall or room of audience. The Atrium was the most important and usually the most splendid apartment. Here the owner received his crowd of morning visitors, who were not admitted to the inner apartments. Originally the Atrium was the common room of resort for the whole family—the place of their domestic occupations; and such it probably continued in the humbler ranks of life. It consisted of a large apartment roofed over, but with an opening in the centre, called *compluvium*, towards which the roof sloped so as to throw the rain-water into a cistern in the floor called *impluvium*.

In building a marine villa, a Roman Atrium might be introduced with utility and effect; and we can conceive nothing more delightful than the enjoyment of the warm sea-breeze of summer in the cool shade of an Atrium, with a portico open to the sea. In such a design, the Atrium, with its portico, should form the centre feature, and the apartments and offices of the occupants should be arranged round the back and two sides; the Atrium, with the portico, being placed towards the sea, would give a full view of it.

A'TROPA, is the botanical name for the genus of plants which includes *belladonna*, or *deadly nightshade*, and *mandrake;* both of which are very poisonous, except when carefully prepared as medicines.

ATRO'PIA, a vegetable alkali which is found to exist in the juice of the *atropa belladonna*, and in which the poisonous qualities of the plant reside. Atropia forms long transparent colourless crystals which are insoluble in cold water, and very slightly soluble by boiling water and alcohol. It forms with acids peculiar salts, which readily crystallize. During the evaporation of a salt of atropia, the vapour which rises occasions an enlargement of the pupil of the eyes of those exposed to its influence, which continues for several hours.

ATTALE'A is the botanical name for a genus of plants, which includes many species highly valuable to the natives of South America. One species, called by the natives *piaçaba* is found in the native forests of the maritime provinces of Brazil, where it is one of the most valuable gifts which the bountiful hand of nature has conferred on man. The best cordage in America, for naval purposes, is manufactured from the fibres of the leaf-stalks and other parts: such ropes are of great strength, and are extremely durable in salt water. No other cables are employed in a great part of the Brazilian navy. Another species, the *pindova* of the old writers on Brazil, and the *indajà* of the modern Portuguese, forms delightful groves in the interior of the country, growing from twenty to fifty feet clear of its branch-like leaves. The latter are from fifteen to twenty feet long, and about three feet wide. The fruit is the size of a goose's egg, and contains an eatable kernel, of which the negroes are fond. Its leaves form an excellent thatch, and are woven into hats, mats, and baskets. Another species furnishes the nuts which the Brazilians burn for the purpose of smoking the juice of *Siphonia elastica*, or Indian rubber, until it becomes black.

ATTAR (or OTTO) OF ROSES, is an essential oil obtained in India from the petals of the *Rosa centifolia* and *R. sempervivens*, by evaporation from the steeped petals, the attar rising to the top of the water as a kind of yellowish scum. It is a very powerful perfume, and is said by Saussure to be a mixture of two oils, one solid and the other fluid at the common temperature of the air.

Attar of Roses liquefies at about 85° of Fahrenheit, and the solid oil at about 91°; the latter crystallizes by cold into brilliant white transparent laminæ of the consistence of bees' wax.

The Attar is produced in two ways. In one method the rose-leaves are carefully distilled, to produce rose-water of a certain degree of strength; this is poured on a fresh heap of rose-leaves, and distilled to produce stronger rose-water; and this latter (a highly fragrant liquid) is poured into shallow vessels, and left exposed to the fresh air during one night; in the morning the attar or essential oil is found to have collected in a thin film on the top. In the other method, rose-leaves steeped in water are exposed in open vessels to the action of the sun for several days, by which time the attar has collected on the surface of the water.

So intense is the odour of attar of roses, that a morsel on the point of a needle will scent a room during a whole day. One hundred pounds weight of rose-leaves are required to produce only three drachms of attar, even under favourable circumstances; and this will suffice to explain the enormous price of this perfume, when pure.

ATTIC, as a term in building, is applied to the upper room or rooms of a house, with or without a parapet-wall in front. But in architecture the attic comprehends the whole of a plain or decorated parapet wall, which terminates the upper part of the façade of an edifice. There is at Athens a monument, that of Thrasyllus, with an attic over the order of pilasters which form the basement; in the centre was a colossal statue. This example may be taken as the best type of a Greek attic which is at present known. Another example, which bears a closer resemblance to the Roman attic, exists in the upper wall of the nave of the Temple of Jupiter Olympus at Agrigentum, where there is an entire wall with short pilasters at intervals, in the front of which are figures placed above the pilasters of the nave. The attic is a conspicuous feature in the triumphal arches at Rome, and a necessary one: it was not merely intended as a frame-work for the inscription, nor as a support for statues, but is essential to the proportions of the composition.

In all the best examples, and especially in the remains of antiquity at Rome, the attic is decorated with a moulded base and cornice, often with pilasters and figures, as in the arch of Constantine.

The Italian architects who had studied the remains of antiquity in Rome, and those who followed in their school, usually employed an attic in their designs. The attic is in such common use, that there are few public buildings in London without it. Somerset House, in the view towards the street, may be taken as offering a very fine example of this feature of an edifice.

ATTRACTION, in its scientific meaning, denotes that quality by which the bodies of the universe, or the molecules of the same body or of different bodies, approach one another when not prevented from doing so. The tendency by which bodies when unsupported approach the earth is called *Gravitation;* that by which the minute particles of bodies are held together is called *Cohesion;* that by which particles combine together chemically is called *Affinity;* while those actions which exist between the particles of the electrical and magnetic fluids, or between these and the particles of bodies, are called *Electrical* or *Magnetic attractions*.

So far as they have any place in this work, these forms of attraction are briefly noticed under the headings just indicated.

ATTWOOD'S MACHINE. This apparatus was invented by George Attwood, a fellow and tutor of Trinity College, Cambridge, towards the close of the last century. It is intended to demonstrate the law of the velocity of falling bodies.

Suppose weights of six and seven pounds hang over a pulley, the weight and friction of which we neglect for the present; if both weights were six pounds, the machine would not move: therefore, the moving pressure is the one pound by which the one weight exceeds the other. This weight, if it had only its own mass to move, or if it fell freely, would generate $32\frac{1}{6}$ feet of velocity per second; but before this system can move, $6 + 7$, or 13 lbs. must be stirred by 1 lb., and there will only be the 13th part of $32\frac{1}{6}$ feet of velocity produced in one second, that is, about $2\frac{2}{5}$ feet. Therefore, in one second, the heavier weight will fall only $1\frac{1}{5}$ foot; and in five seconds, 25 times as much, or 30 feet. And the velocity acquired may be reduced in any proportion, by making the weights more nearly equal.

Attwood's machine is a pulley, the pivots of which, instead of being placed in a block, are sustained on friction wheels, to diminish the friction. Two weights are hung over this by a string, and the mass moved consists of the two weights, the pulley, and the friction wheels.

The length described in any time is measured by a vertical scale of feet, placed close to the line of motion of one of the weights. To measure the velocity acquired at any point the moving pressure (the excess of one weight above the other) must be taken off, in order that there may be no fresh accession of velocity, or that the system may proceed only with the velocity acquired. This is effected by making the larger weight in two parts, one part equal to the smaller weight, and the other of course to the excess or moving pressure. The latter is so formed that it cannot pass through a certain ring, while the former can. By fixing this ring to any required point of the scale of feet, the moving pressure is taken off when the larger weight passes through it.

Attwood's machine is not wholly satisfactory; but of the four principles—1, the law of uniformly accelerated motion: 2, the constancy of the retardation caused by the having to communicate every acceleration also to the pulley and friction wheels; 3, the constancy of the retardation arising from friction; 4, the smallness of the resistance of the air to small velocities—this machine may be made to prove any one to a spectator who admits the other three.

AUBE. This department of France, formed out of portions of the former provinces of Champagne and Burgundy, possesses a little mineral wealth; iron is found, but no mine is worked; limestone is abundant; building stone, potter's clay, marl, and pipe-clay are found. Turf also is found in some districts, but the fuel of the department is supplied by its forests, the principal of which are those of Clairvaux, Chaource, Montmorency, Orient, and Soulaines.

The principal manufactures are broad cloth, cotton, stuffs, and hosiery. Leather, coarse cloth, cambric, silk, linen, and gloves are also made. Besides these fabrics the department has numerous potteries, tile, porcelain, and glass-works, paper mills, distilleries, vinegar yards, beet-root sugar factories, rope-walks, starch factories, dyeing and bleaching establishments. The trade of the department is in the agricultural and manufacturing products already mentioned, together with cheese, wool, sausages, firewood, and charcoal.

The chief towns in which the manufactures are centred are Troyes, Mery-sur-Seine (the centre of a great honey district containing above 3000 hives), Piney (where there is a large manufacture of ropes and mats from the bark of the lime-tree), Arcis-sur-Aube (where cotton spinning and dyeing are carried on), Ricey (a good wine district), Villenaux, Romilly (where there are several oil and corn-mills), Nogent, Bar sur-Aube, &c.

AUCH, the capital of the department of Gers in France, has a trade in wine, brandy, wool, quills, and fruits; woollen and cotton stuffs, leather, crape, and hats, are manufactured in the town and neighbourhood.

AUCKLAND ISLANDS. These remote islands, lying about 200 miles south of New Zealand, were discovered by Captain Briscoe in 1806. A commercial interest is attached to them at the present time arising out of an attempt to colonize them and make them a depôt for the Southern Whale Fishery.

The Auckland Islands have been granted by government to the Messrs. Enderby on very advantageous terms, in consideration of the services rendered by their father to this country, as also for the more recent discoveries of the southern continent by Captain Briscoe whilst in the employ of the Messrs. Enderby. A company, to which the Messrs. Enderby have ceded their privileges, obtained a charter of incorporation on the 16th of January, 1849, for the purpose of prosecuting the southern whale fishery from the Auckland Islands; and Laurie Harbour has been chosen as the head station of the company, from the superior facilities it affords to whaling vessels. The islands were uninhabited until the Southern Whale Fishery Company, under the conduct of one of the Messrs. Enderby, made a settlement there in 1849. At the first annual meeting of the company, held in February 1850, it was stated that the company had despatched a store-ship, an emigrant ship with settlers, and three whale ships to the island; and that others would soon follow. Quite recently (Nov. 1850) accounts have been received, detailing the successful commencement of the settlement.

AUCTION, a method employed for the sale of property. The Romans gave it the descriptive name of *auctio*, an increase, because the property was publicly sold to him who would offer most for it. In modern times a different method of sale has been sometimes adopted, which is called a Dutch auction, thus indicating the local origin of the practice: it consists in the public offer of property at a price beyond its value, and then gradually lowering or diminishing that price until some one consents to become the purchaser. Fish is often sold in this way on the beach near the fishing-towns. The system adopted at the Cornish mines is a sort of medium between the ordinary and the Dutch auctions; two months' mining is let to a gang or a party of miners who bid the *lowest* sum, that is, who agree to take the smallest per centage of the produce for their reward.

Persons are now sometimes invited to a 'sale by the candle,' or 'by the inch of candle.' The origin of this expression arose from the employment of candles as the means of measuring time, it being declared that no one lot of goods should continue to be offered to the biddings of the persons who were present for a longer time than would suffice for the burning of one inch of candle; as soon as the candle had wasted to that extent, the then highest bidder was declared to be the purchaser.

AUDE, a department of France formed of a portion of the old province of Languedoc, has a fair proportion of produce and manufactures. Mines of coal, plastic clay, and plaster of Paris are profitably worked; limestone, good building stone, and slate are found. The Corbières Mountains contain mines of antimony, manganese, copper, lead, and silver; but none of them are worked. There are several mineral and salt springs. Marble of great beauty is found among the transition limestone and the lower secondary strata in the quarries of Cannes.

The chief manufacture of the department is fine broad cloth, for making which wool is imported from Spain; leather, hats, hosiery, paper, and pottery are made. There are numerons distilleries, flour-mills and saw-mills, furnaces and iron foundries. The exports of the department consist of soda, which is found abundantly on the coast of the Mediterranean; salt, of which about 90,000 tons are annually made in the salt-pans in the neighbourhood of Bages and Sigean; boxwood combs, jet ornaments, and the agricultural, mineral, and industrial products before named.

Besides Narbonne, the chief manufacturing town is Carcassone, where there is a considerable commerce in mineral products, wine, corn, fruits, &c.; but the town is principally engaged in the manufacture of fine broad cloth, blankets, hosiery, woollen yarn, and linen. There are also several brandy distilleries, soaperies, dye-houses, paper-mills, and naileries in the town. Limoux has important manufactures of broad cloth: there are also woollen-yarn manufactories, tanneries, soaperies, and oil-mills. Limoux has a considerable trade in wine, and is the mart for the iron of the neighbouring furnaces. Castelnaudery has manufactures of coarse cloths, canal boats, pottery, and bricks; there are also brandy distilleries and flour-mills; besides the articles named, the town trades in timber, iron, and hides.

AUGER. The auger is an instrument for boring holes in wood, larger than can be made with an awl or a gimlet. In its simple form, this instrument is too well known to need description. A few years ago a new kind of auger was invented, and introduced into some of our manufacturing establishments; it differs from the common auger in having a spiral like that of a corkscrew, which empties itself of the fragments of wood without having need to be withdrawn from the bore.

AUGITE, a mineral which presents many varieties according to its mode of production. Mineralogists have discussed at much length the connection between augite and hornblende, and their probable formation. Mitscherlich has observed that at many iron-foundries in Sweden and Germany the scoriæ possessed the form, structure, and chemical composition of certain minerals found in nature. From this source he has been led to the opinion, that augite is formed whenever the process of cooling, and consequently of crystallization, is rapid; and horn-blende, when it is conducted more slowly: the chemical ingredients being in both cases nearly the same.

AUGSBURG, the capital of the Bavarian circle of the Upper Danube, is distinguished in commercial matters by its banking and exchange operations, and by its transit of merchandise. It is a staple town also for the deposit and sale of the wines of Italy, Switzerland, and the south of Germany. It has above 200 mercantile establishments, and an annual circulation, varying in value from three to four millions sterling, in bills and merchandise. Augsburg is famous for its plate, jewellery, time-pieces, philosophical and mathematical instruments, books, prints, maps, cotton and woollen manufactures, leather, beet-root sugar, and many other products, which rank it among the chief industrial and commercial cities of Germany.

The manufacturers of Augsburg are making preparations to represent the industry of their town and the surrounding district, in the approaching Industrial Exhibition in Hyde Park.

AUGUSTOVO, one of the districts of Russian Poland, produces considerable quantities of wild hops, which form an article of export to Königsberg. It is likewise rich in forests, those which skirt the Memel being full of linden trees, whence the celebrated 'linden-honey.'

AUK, is a family of oceanic birds, of which some of the species yield products of merchantable value. The razor-bill auk abounds on the shores of Labrador, where thousands are killed for the sake of the breast feathers, and vast numbers of eggs are collected. This species also visits the cliffs of the Isle of Wight, the Isle of Man, and the Scottish isles; where the eggs, which are esteemed a delicacy, are taken in great numbers; but the means by which they are obtained is perilous, and requires no little nerve. A large stake or bar of iron is driven into the top of the cliff (five or six hundred feet in height), and to this is fastened a strong rope, at the end of which a stick is put crosswise, on which rides the adventurer, who is lowered down the front of the precipice. If his object be to secure the eggs only, he shouts to scare the birds away, which rise in countless numbers, uttering discordant cries; but if his object be the feathers, which are valuable, he goes to work in silence, and knocks down all the birds within his reach. The flesh is worthless, but is used by fishermen as a bait for crab-pots, &c. This plan is practised in the Isle of Wight, in the Isle of Man, and the Feroe Islands, as well as along the coast of Norway.

AURANTIA'CEA. A few details respecting the fruits thus named will be found under LEMON; ORANGE.

AU'REUS, or DENA'RIUS AUREUS, was the ordinary Roman coin of gold. It was equivalent to twenty-five silver denarii, or a hundred sestertii.

Gold was first struck at Rome B.C. 207. The earliest coin of gold at this time was named a scruple (scrupulum), and went for twenty sesterces of that age. Pliny says, that it was afterwards usual to coin forty pieces out of the pound of gold (larger of course, bearing the general name of Aurei), and that the Roman emperors by degrees made them forty-five to the pound. The aureus was sometimes called solidus, as opposed to a half and a third. A constitution of Valentinian and Valens declares that the pound of gold must be considered as 72 solidi. An aureus of Julius Cæsar, in the British Museum, weighs 123 grains, which is exactly the weight of an English sovereign, but the Roman coin contains no alloy, or very little. Of the aurei of Constantine in the Museum, one weighs 66 grains, three 67, three 69½, one 73½, and one 81½. The average weight of the aurei of Augustus appears to have been nearly 121 grains; that of Nero's aurei nearly 117.

AURICH, a province (*landrostei*) of Hanover, has a few industrial features to recommend it to our attention. Its inhabitants grow grain, particularly oats and rapeseed; breed great numbers of horses, sheep, and cattle; make much honey; export great quantities of turf; and are actively engaged in foreign commerce and the herring-fishery on the Scotch coast. Besides the town of EMDEN, Aurich contains the busy town of Norden, which has timber and dockyards, tanneries, breweries, distilleries, tobacco and woollen factories.

AURILLAC, capital of the department of Cantal in France, carries on manufactures in paper, lace, copper, household utensils, and leather; the chief trade is in cattle, cheese, stockings, tapestry, and lace.

AURUNGABAD, like many other cities in India, carries on a considerable traffic in the bazaar, where both European and native goods are exposed for sale; the principal trade is in silk manufactures, mostly of Indian workmanship.

AUSTELL, (ST.) or ST. AUSTLE, is the centre of one of the rich mining districts in Cornwall. It first rose to eminence from its vicinity to the great tin mine of Polgooth and other considerable mines. Polgooth is partly in this parish, and was at one time esteemed the richest mine ever worked in England; it is still productive, the working of it having been recently recommenced. The town still owes its principal importance to the mines, and has formed harbours at Charlestown and Pentewan for the convenience of importing coals from Wales, and of exporting the ores or porcelain clay of the district. A railroad connects the town with the harbour of Pentewan. There is a smelting-house at the west end of the town, and another at Charlestown. Copper ore is said to have been smelted at St. Austell before any other place in Cornwall.

AUSTEN, WILLIAM, an English metal-founder of the fifteenth century, is worthy of a brief notice in this place, in so far as he had a great share in the construction of the celebrated tomb at Warwick, in St. Mary's church, of Richard de Beauchamp, earl of Warwick, who died in 1439. In a document given in Dugdale's 'Warwickshire,' William Austen is styled, 'citizen and founder of London,' from which and the details of the agreement, it appears that he was not the designer or modeller of the figures which he cast in brass, for it is expressly stated that he is to work from models made of timber. 'Will. Austen, citizen and founder, of London,' xiv. Martii, 30 H. 6, covenanteth &c. to cast, work, and perfectly to make, of the finest latten (brass) to be gilded, that may be found, xiv. images embossed, of lords and ladies in divers vestures called weepers, to stand in housings made about the tomb, those images to be made in breadth, length, and thickness, &c., to xiv. patterns made of timber. Also he shall make xviii. less images of angells, to stand in other housings, as shall be appointed by patterns, whereof ix. after one side, and ix. after another. Also he must make an hearse to stand on the tombe above and about the principal image that shall lye in the tomb according to a pattern; the stuff and workmanship to the repairing to be at the charge of the said Wil. Austen.

'The said William Austen, xi. Feb. 28 H. 6, doth covenant to cast and make an image of a man armed, of fine latten, garnished with certain ornaments, viz. with sword and dagger; with a garter; with a helm and crest under his head, and at his feet a bear musted (muzzled), and a griffon perfectly made of the finest latten, according to patterns; all of which to be brought to Warwick and laid on the tombe, at the peril (risk) of the said Austen.'

In the opinion of Flaxman, these works of Austen are equal to what was done in Italy at the same time; and though he is mentioned only as the founder, he may possibly be the designer of the figures, as the patterns spoken of in the covenant may have been made in relation to size and costume, and not as exact models to prepare the casts from. The monument, one of the earliest and best in England, is still in a good state of preservation, and is of brass; the meaning therefore of the word latten, which has been disputed, is evidently brass.

AUSTRALIA. The time is not far distant when this island, the largest on the globe, will possess a high degree of commercial importance. All our colonies on its shores—New South Wales, Port Phillip, South Australia, and Western Australia—are gradually advancing in industry and in commerce. The first three are becoming rich in sheep and its produce, while South Australia is also contributing the riches of its mineral produce.

The mineral riches of Australia are being yearly more and more explored. Iron, coal, copper, tin, and lead, are known to exist—some in large quantities. There were in 1847, in South Australia alone, 27 copper mines, 1 lead mine, 2 copper and lead mines, and 1 copper and gold mine. On the estate of the Australian Agricultural Company, near Newcastle, coal was found in 1849; and it was expected that mines would be ready for working on that spot by the beginning of 1850. In 1847 Dr. Van Sommer explored, in a geological survey ordered by the governor, a vast bed of coal in Western Australia, which bids fair to realize the hopes of that hitherto unsuccessful colony; and in 1850 ebony, sandalwood, and guano, have begun to occupy a place among the exports from this colony. Limestones, sandstones, clays, gypsum, roofing slate, are among the abundant materials of manufactures.

From the latest returns from Australia, we find that copper is now offered for sale in considerable quantities. A brig has sailed thence during the present summer to Singapore, with 246 tons of fine tough copper, worth 20,000*l.*; this was collected from four of the South Australian copper works. The value of the mineral produce exported from that colony has increased with surprising rapidity—as thus:—

1843	128*l.*
1844	6,437*l.*
1845	19,019*l.*
1846	142,231*l.*
1847	174,017*l.*
1848	320,624*l.*

This Australian copper finds a market in Germany and in France, as well as in England; its quality is said to be very fine. In August 1850, the shares of no fewer than 21 Australian copper mines were in the market, most of them commanding high prices!

The wool trade of Australia, also, is becoming of vast importance. The export of wool from the various colonies of the island in 1847 was about 20 millions of pounds; in 1848 it exceeded 30 million pounds; and in 1849 it rose to the amount of 35 millions.

Efforts are now being made to establish a mail steam-packet route from England to Australia. Four routes are advocated by different interests—1st, across the Isthmus of Panamá and the Pacific; 2nd, by the Cape of Good Hope; 3rd, by Singapore and Western Australia to Sydney; 4th, by Singapore and North Australia to Sydney. The first three routes are each, in round numbers, about 13,000 miles; the fourth is rather over 12,000. One of the Singapore routes, by placing Australia in connection with India and China, as well as with England, will probably be selected as most advantageous; but an unfortunate difference of view between the government and the East India Company at present exists on this point. It has been recently shown, that the voyage from Australia to England by the system of what is termed Great Circle sailing, effects a saving in distance of nearly 900 miles, over the old sea route.

Australia will contribute to the Exhibition of 1851.

AUSTRIA. This large empire has been formed by the annexation of so many kingdoms and states, and embraces so great a diversity of soil and productions, that we can only briefly notice its chief industrial features.

Slavonia and the south-eastern and central parts of *Hungary* are richer than most European countries in metals and minerals. Slavonia is traversed from east to west by mountains and hills; and this province, as well as *Croatia*, has alternations of plain and highland which are very fruitful in grain, wine, tobacco, silk, honey, and other products. *Transylvania* being mountainous, the produce is chiefly timber and minerals. *Galizia* is, next to Hungary, a principal granary of the Austrian states, and supplies large quantities of salt, some precious metals, and many other mineral and vegetable productions; but the climate is too cold for the grape. Austrian *Silesia*, next adjoining Galizia, is abundant in pasture and timber, but not in grain. *Moravia*, in its central and southern parts, is a rich land of maize and wine. *Bohemia* has rich and abundant produce. *Upper and Lower Austria* are poor in grain; but fruit, wine, and salt are procured in abundance. The adjoining province of *Styria* is well supplied with pastures, and is besides rich in mineral produce. Next to this is the *Tyrol*, in which the chief products are horses and cattle, grain, wine, fruit, potatoes, timber, salt, iron, copper, silver, lead, and a little gold. *Illyria*, which is composed of *Carinthia*, *Carniola*, and some smaller provinces, includes more varieties of climate and productions than any other part of the Austrian empire. *Dalmatia*, southward of Illyria, supplies much produce, which consists chiefly of marble of excellent quality, wine, oil, figs, almonds, wax, horned cattle, sheep, salt, and more particularly fish. *Austrian Italy* produces grain, maize, rice, millet, peas, beans, potatoes, hemp, flax, vegetables and fruits of all kinds, and, in some parts, saffron; there is no branch of industry more carefully or profitably cultivated than the production and manufacture of silk. The *Alpine* districts yield considerable quantities of iron, copper, coal, marble, and other minerals.

The principal plants cultivated in Austria comprise all the usual kinds of grain, fruit, and vegetables. The chief medicinal plants are—rhubarb, which is raised in Styria, the Lower Ens, Bohemia, and Galizia; liquorice, a favourite article of growth in Moravia, whence 400 tons and upwards are annually exported, and which is also gathered in the wild state in Hungary and Slavonia; manna, derived from the *Fraxinus ornus*, which abounds in the forests of Hungary and Slavonia; and spikenard (*Spica Celtica*), which is collected with much care in the mountains of Carniola, Styria, the Tyrol, and the Upper Ens. An intoxicating spirit is distilled in Carinthia and Styria fram gentian, which is found in most of the elevated regions; and Iceland-moss is collected in considerable quantities on the Carpathian mountains, where it grows in masses of five and six feet in height.

More than one-third of what is deemed the available soil of the Austrian dominions is occupied by woods and forests; and wood is one of the staple productions. Among the products of the Austrian forests we may name potashes, which are chiefly made in Hungary, Galizia, and the Buckowine, Moravia, the Archduchy, and Bohemia. Tar, charcoal, gall-apples, and turpentine should be added to this enumeration of the products of these forests, though they are not of considerable moment.

The quantity of wine annually made in the Austrian territory averages about 3,200,000,000 gallons; of which Hungary produces more than one-half, and of which the inhabitants of the empire are said to consume about seven-eights. Tokay is a Hungarian wine, very choice, but small in quantity.

The rearing of the silkworm, though not wholly neglected in other parts of the south of Austria, is nowhere carried on to such an extent as in the territories of Lombardy and Venice. The whole produce of the empire is estimated at about 6,000,000 lbs., of which about 4,500,000 lbs. are the produce of the Italian provinces. A considerable proportion of this article in the wrought state, chiefly of the sort termed organsine, is exported from the Italian provinces to the English market. Cantharides, or Spanish flies, are a considerable article of export from Hungary and Slavonia; the cochineal insect draws many purchasers into the sandy tracts of Galizia from Turkey and Armenia; and the leech of late years has become an article of considerable trade between Austria and France.

Among the other productions of this monarchy, we may notice that tobacco is a monopoly engrossed by the department of finance in every province but Hungary, Transylvania, and the Tyrol. The annual produce of Hungary alone amounts to 330,000 cwts. There are private manufactories in the three provinces to which this monopoly does not ex-

KNIGHTS CYCLOPÆDIA OF THE Industry of all Nations.

tend. Of seed-oil, though the produce is very considerable in all quarters, enough is not manufactured for the consumption. Large quantities of olive-oil also are obtained from the territories of Lombardy and Venice, particularly the neighbourhood of the Lago di Garda, Illyria, and Dalmatia. The manufactures of paper and of glass are very extensive, and employ a large number of hands.

In *Mineral Productions* Austria surpasses every other country in Europe. With the exception of platinum, it would be difficult to name any metal which it does not possess. The richest of its gold-mines are in Transylvania, which has been called the gold-mine of Europe, and in which no less than forty mines are worked. Silver is largely produced in Hungary; and in smaller quantities in other districts. Schemnitz is the great mining capital for the gold and silver districts. Copper mines and works exist in different parts of the empire: and the annual supply of copper which is raised in the Austrian dominions would appear to amount to about 2500 or 3000 tons. More than double this quantity of lead is produced. Iron is a metal of which almost inexhaustible resources exist, though, on account of the dearness of fuel, the mines have not yet been turned to any very extensive use: the quantity raised throughout the empire is about 80,000 tons per annum. In the Huttenberg, Carinthia possesses one of the oldest and at the same time one of the richest iron mines in Europe, its produce being from 8000 to 9000 tons a year. Tin is raised in no part of Austria but Bohemia, and the whole produce does not exceed 2000 cwt., which is far short of the consumption. The quality, however is good. There is no mine of quicksilver in Europe so rich as the mine at Idria in Carniola. Calamine and zinc are obtained from the Tyrol, the Archduchy, Styria, and Bohemia; cobalt from Hungary, Styria, and Bohemia; arsenic from Hungary, Transylvania, Bohemia, and Salsburg; antimony from Hungary, Transylvania, the Tyrol, and Bohemia; chrome from the Tyrol; and bismuth and manganese from Hungary.

The various species of salt, such as sea-salt, rock, and that made from brine-springs, exist in abundance. The celebrated mine of Wieliczka, which has been worked ever since the year 1253, and lies in the north-western part of Galizia, is but an inconsiderable inroad upon a massive bed extending for a length of nearly 600 miles along the Carpathians, as far as Okna in Wallachia. The whole salt produce of the empire amounts to nearly 300,000 tons yearly. Vitriol, alum, saltpetre, and soda, are among the mineral produc

Wood fuel is much more used than coal or peat; yet there is considerable abundance of these. Every part of the Austrian dominions possesses more or less of native sulphur, but more particularly Galizia, Hungary, Transylvania, and Bohemia. Mineral tar and oil are chiefly obtained in Galizia and the Buckowine; but they are also produced, though but partially turned to account, in the Archduchy, Hungary, Bohemia, Illyria, and Dalmatia.

Among precious stones, the Bohemian carbuncle and Hungarian opal stand in highest repute. The chalcedony, ruby, emerald, jasper, amethyst, topaz, carnelian, chrysolite, and beryl, as well as what is called the 'marble diamond,' in Hungary, must be added to the list of Austrian precious stones. Marble of every description and variety of colour and vein is raised either in Hungary, Transylvania, Bohemia, the Archduchy, Tyrol, Styria, Illyria, Dalmatia, or the Italian possessions of Austria, in which latter the Veronese alone is said to possess 106 distinct varieties. Carinthia and Styria, indeed, supply a quality of white marble no way inferior to the Carrara marble. Alabaster, serpentine, black tourmaline, gypsum, black-lead, slates, and flint, are among the mineral produce.

The principal seats of the linen manufacture, or rather of those productions in which flax and hemp are employed, are Bohemia, Moravia, and Silesia, which furnish the finest articles of this description in Austria, though in diminished quantities as compared with the earlier part of the present century. For variety and goodness of manufacture, the states of Lombardy and Venice deserve to be classed in the next rank to those three provinces. The Tyrol, Hungary, Galizia, and Transylvania produce scarcely any but the middling and coarser species of linen; nor is there much beyond what is termed house-linen made in the Archduchy, Illyria, or the Military-Frontier districts. The raising and preparation of flax alone in Austria are estimated to give employment to 750,000 individuals, and its native manufactures to yield sufficient not only for domestic use, but for partial exportation.

The largest manufactures of woollens, both cloth and other kinds, are established in Moravia and Bohemia. These products in both countries are said to be as much distinguished for their excellence as their variety. In the other parts of the empire, where this branch of industry is proportionably pushed to a much less extent, the principal articles manufactured are of middling and coarse quality, whilst the finer sorts, so far as their domestic consumption requires it, are of Moravian and

Bohemian fabric. Considerable quantities of the latter are exported to foreign parts. The woollen manufacture employs at least 320,000 Austrian hands; and the crown has given no small impulse to it by erecting several establishments, conducted at its own expense, among which is that at Linz, which employs 10,000 spinners and weavers.

The silk manufactures have been rapidly extending in Austria since the introduction of Jacquard's machinery. They are principally carried on in the province of the Lower Ens, and in the Milanese and Venetian territories. The cotton manufacture, though it has been prosecuted with some energy, especially near Vienna, can hardly be said to be prosperous, owing to the difficulty of competing with England and other countries.

The province of the Lower Ens takes the lead in the manufacture of leather, of which the best qualities are made in Vienna. The Upper Ens, Moravia, Styria, Bohemia, and the Tyrol rank next in importance. Hungary abounds in tanneries; and in fact nearly every province in Austria is engaged more or less in this branch.

Iron, the mines of which have been already alluded to, is wrought into marketable form in many parts of the empire. Cast iron is produced in Bohemia, Styria, Hungary, and Illyria; bars and sheets are rolled in the Lower Ens, Styria, Carinthia and Bohemia; iron and steel wire are made in the Archduchy; nails in many of the provinces; and fire-arms and swords in Styria and Hungary. Manufactories of copper, brass, cannon, tin, lead, balls and shot, buttons, gold and silver, are maintained in various parts of the empire.

It was estimated by Lichtenstern, Stein, and Malchus, a few years ago, that the number of manufacturers employed in working up the native produce of Austria, or the raw materials imported from other countries, amounted to 2,365,000, and the yearly value of their productions to 1425 millions of silver currency, representing a sum in British sterling of upwards of 140 millions.

With respect to external trade, no country of equal extent is perhaps more disadvantageously situated; its line of sea-coast is comparatively inconsiderable, and with the solitary exceptions of the Po and the Adige, its finest streams, such, for instance as the Danube and Elbe, lie, even when crossing its frontiers, at a considerable distance from the sea.

Considerable preparations are being made in various parts of the Austrian empire, especially Vienna, to hold a worthy position in the Industrial Exhibition of 1851. The manufacturers hope to produce articles in which combined *cheapness* and excellence will be characteristics. Viennese pianofortes, especially, are expected to illustrate this combination—a feature of much value.

AUTO'MATON, derived from two Greek words, meaning *self-moved*, is a name generally applied to all machines which are so constructed as to imitate any actions of men or animals.

The pigeon of Archytas, the clock of Charlemagne, the automaton made by Albertus Magnus to open his door when any one knocked, the speaking head of Roger Bacon, and the fly of Regiomontanus, are early examples of such machinery, respecting which, however, we have too little information to afford a correct judgment concerning them. In more recent times we read a marvellous account of an automaton group constructed by M. Camus for the amusement of Louis XIV., consisting of a carriage and horses, with a lady who alighted to present a petition; and also, in the 'Memoirs of the Academy of Sciences' for 1729, of a set of actors representing a pantomime in five acts. Less marvellous, though highly ingenious, was the automaton flute-player of Vaucanson, exhibited at Paris in 1738. The same ingenious person subsequently produced a figure which played the flageolet and tambourine; and a duck, which not only imitated the motions and sounds of a real duck, but swallowed food, and digested it by means of chemical substances in the stomach. More recently M. Maelzel exhibited at Vienna an automaton trumpeter; and automata have been made to write, to draw, and to play on the piano-forte. The automaton chess-player is now known to have been worked by a person concealed inside the figure and its table or pedestal, which supposition, however, does not deprive its maker of the credit of great ingenuity in the mechanism by which the hands were set in motion.

The passion for making automata has not yet quite passed away. A recent example was Mr. Faber's *Euphonia*. It consisted of a draped bust and waxen-faced figure, which articulated language with a certain degree of intelligibility. The sounds were produced by striking on sixteen keys. A small pair of bellows was worked with the nozzle in the back part of the head of the figure; and in the head were various arrangements of India rubber and other materials, calculated to yield a particular sound in each part or section. When the exhibitor wished to produce a sentence or word, he first mentally divided it into as many parts as there are actually distinct sounds—not necessarily coinciding with the syllables or the single letters; since the various phonographic systems far more correctly represent distinct sounds. Having determined the first word, the operator pressed his finger on a particular key, which admitted a blast of air to a particular compartment, in which the mechanism was of the kind to produce the sound required. Other keys were similarly pressed, until all the required sounds of the word or sentence were produced. The sounds were near enough to those of the human voice to convey the meaning intended, but they had an unpleasant effect to the ear. By a modification of the action, whispering was imitated.

A remarkable machine was the *Automaton Latin Versifier*, introduced in 1845, by Mr. John Clark of Bridgewater, after a labour of thirteen years. At the first thought such an invention seems inexplicable, owing to the mental character of the process; but a little enquiry shews that it is only a system of permutations, such as a machine can easily be made to produce. The specimens given in the 'Athenæum' and other public journals at the time, are all Latin hexameters, and moreover have all the same grammatical formula and scansion, in respect to dactyls and spondees. The following nine specimens are given, each complete in itself, as an hexametric line, but having no connexion with the others.

1. Horrida sponsa reis promittunt tempora densa.
2. Sontia tela bonis causabunt agmina crebra.
3. Bellica vota modis promulgant crimina fusca.
4. Aspera pila patet depromunt prælia quædam.
5. Effera sponsa fere confirmant vincula nequam.
6. Barbara tela reis præmonstrant nubila dura.
7. Horrida vota bonis progignunt jurgia crebra.
8. Sontia castra modis prositant somnia fusca.
9. Trucida regna quidem conquirunt opera cara.

The exterior of the machine which composes these lines resembles in size and shape a small bureau book-case; in the frontispiece of which through an aperture, the verses appear in succession as they are composed. Mr. Clark, in a communication to the 'Athenæum' (No. 923) makes the following observations on his machine, which he calls the *Eureka*:—"The machine is neither more nor less than a practical illustration of the law of evolution.............. The machine contains *letters* in alphabetical arrangement; out of these, through the medium of numbers, rendered tangible by being expressed by indentures on wheel-work, the instrument selects such as are requisite to form the verse conceived: the *components* of words suited to form hexameters being alone previously calculated, the harmonious combination of which will be found to be practicably interminable.'

Mr. A. J. Cooley, in the same journal, pointed out the existence of a forgotten pamphlet, a century and a half old, in which the author showed how, from a table given, a person might produce millions of hexameter lines. But these were produced by accumulations of words; whereas Mr. Clark's machine, if we rightly understand his description, actually builds up the lines letter by letter.

It is matter of regret that so much ingenuity should be expended in the production of useless results. There are, however, many machines—for calculating, numbering, registering, stamping, paging, &c.—which will be described in various parts of this work, and which illustrate the application of automatic action to useful purposes.

AUTOPHON, is the name given by Mr. Dawson, the organ builder, to an ingenious little contrivance, whereby a barrel organ can be made to play an unlimited number of tunes, instead of the limit usually placed to its action. The tunes or the notes representing them are perforated on sheets of millboard, one to each tune; when one of these is placed within the instrument, the pipes can only sound (on the handle being turned) according to the perforations; so that the tune played depends on those perforations, and not on any particular arrangement of studs in the barrel. There is much of the principle of the Jacquard apparatus in this contrivance. As the perforated tune-cards are sold at a few pence each, a large variety of tunes can be made available. We believe the primary object of the inventor is to make a barrel organ serve for country churches, where it is not convenient to have a player for a keyed instrument. The Autophon was exhibited at the recent Industrial Exhibitions at Dublin and Devonport.

AUTUN, a city in the south of France, is more celebrated for its remains of antiquity than for its industrial features. It has however a respectable amount of trade and manufactures. The trade of the town consists in horses, cattle, wood, and hemp. Serge, cotton-velvet, cloth for regimentals, hosiery, and leather are among its manufactures; and a fabric called *tapisserie de marchau*, fitted for coverlets of beds, horse-cloths, and other purposes, is made. The district round the city contains green porphyry and gray granite; and there are also iron and lead mines near the town.

AUXERRE, a city near the centre of France, stands in a country fruitful in wine. Woollen cloths, serges, druggets, stockings, cotton-yarn, bricks, and pottery are made; but the chief trade of the town is in wine, of which about 4,000,000 gallons are sent by water to Paris and into Normandy. Wood and charcoal are also considerable articles of trade at Auxerre.

AUXONNE, a town near the centre of France, has a cannon foundry and powder mills. The trade is chiefly in wine, brandy, grain, melons, and wood; as well as in cloth, and serges, which are sent to Lyon. In return, groceries, silk, and the wines of Mâcon, are received. There are in the neighbourhood quarries of marble and of various kinds of stone. Turquoises and fossil corals are found in these quarries.

AVANTURINE, a variety of quartz, remarkable for the brilliancy with which it reflects light, the effect being in general produced by fine points of mica imbedded within the crystalline mass. From this circumstance it is sometimes employed in jewellery, but it is of little value.

AVANTURINE GLASS. This name has been given to a species of coloured glass, formerly made at Venice, and applied to the manufacture of trinkets and ornaments. The name is given to it on account of its resemblance to the crystal similarly designated. It consists of a yellowish brown kind of glass, enclosing fine thin yellow laminæ or scales, which have a brilliant metallic lustre.

It does not seem to be clearly known in this country how the Avanturine glass is made. Some suppose that the yellow laminæ are produced by melting scales of metal or mica with the glass; but it is deemed more probable that a salt of copper is mixed and melted with the glass, and that a powerful reducing agent decomposes this salt during the melting, and separates the copper in the state of thin metallic scales.

A *tazza* of Avanturine glass was exhibited in the display of Mediæval Art, at the rooms of the Society of Arts in 1850; and many such are preserved as relics of art.

AVEBURY, or ABURY, in Wiltshire, is remarkable as the site of what appears to have been one of the largest Celtic or Druidical temples in Europe. In forming this temple, no less than 650 blocks seem to have been brought together and placed in circles and rows. These stones were of various dimensions, measuring from five to twenty feet in height above the ground, and from three to twelve feet in width and thickness. One hundred were raised on end, and placed in a circular form, within a flat and nearly circular area of about 1400 feet in diameter; and these stones were bounded by a deep ditch and lofty bank, which inclosed the whole work, except at two places, where openings were left for entrances. The bank or mound at present is broken down in four places, but there seem to have been originally only two openings corresponding to the two great avenues which formed the approaches. The inner slope of the bank measured 80 feet, and its whole circumference at the top was 4442 feet: the area within the bank or mound is somewhat more than thirty-five acres. There were two other small circles within the periphery of the great circle. One was a double circle of upright stones, with a single stone raised near the centre, and consisted of forty-three stones. Another circle, of forty-five stones, some of which are still standing and of immense size, was placed a little north of the former, and consisted also of two concentric circles, inclosing a group of three tall stones. These were the component parts and general design and arrangement of the triple temple, as it may be called; but there were two connecting parts which gave a peculiarity to this work distinguishing it from all other Celtic temples. These were avenues of approach, consisting of double rows or lines of upright stones, which branched off from the central work, each to the extent of more than a mile. One of them branched off from the outer circle to the south, turning, near its extremity, to the south-east, where it terminated in two circular or rather elliptical ranges of upright stones. According to Stukeley, this avenue was formed by two hundred stones, being finished at its eastern extremity with fifty-eight stones, which were arranged in a double circle on an eminence called Overton Hill, or the Hakpen Hill, and measured about 146 feet in diameter from outside to outside. The width of the avenue varied from fifty-six to thirty-five feet between the stones, which were on an average eighty-six feet apart from each other in their linear direction. The western avenue extended about one mile and a half, and consisted of 203 stones; its extremity ended in a point or with a single stone. These avenues or grand approaches to the temple were not arranged in straight lines, but in flowing or curved lines.

Only a few stones now remain of this remarkable specimen of Druidical Art.

AVENA. [OATS.]

AVERAGE is a quantity intermediate to a number of other quantities, so that the sum total of its excesses above those which are less is equal to the sum total of its defects from those which are greater. Thus, 7 is the average of 2, 3, 4, 6, 13, and 14. To find the average of any number of quantities, *add them all together, and divide by the number of quantities.*

The average of a set of averages is not the average of the whole, unless there are equal numbers of quantities in each set averaged; for instance, if a harvest were called good because an average bushel of its corn was better than that of another, without taking into account the number of bushels of the two, this might not necessarily be true. The average quantity is a valuable common-sense test of the goodness or badness of any particular lot, but only when there is a perfect similarity of circumstances in the things compared. For instance no one would think of calling a tree well-grown because it gave more timber than the average of all trees; but if any particular tree, say an oak, yielded more timber than the average of all oaks of the same age, it would be called good, because, if every oak gave the same, the quantity of oak timber would be greater than it is. In Marine Insurance, a sum or contribution determined in the following way, is called an Average. If any part of the ship or furniture, or of the goods, is purposely sacrificed for the sake of saving the rest, all parties interested must contribute towards the loss; and this contribution is the Average, or the share of the loss to be borne by each owner.

AVEYRON, a department in France, part of the ancient province of Guienne, produces 6,000,000 gallons of wine yearly. Between the rivers Lot and Aveyron there is a very rich bed of coal. Besides its valuable coal mines, the department contains mines of copper, lead, zinc, sulphur, antimony, iron, and alum. The lead ores are rich, and contain a considerable quantity of silver. Marble, rock-crystal, kaolin, millstone grit, flint, emery, chalk, marl, plaster of Paris, &c., are found. The abundant water power of the department is applied to good purpose in various factories for the manufacture of paper, iron, cotton, leather, woollen stuffs, &c. The trade of the department is in the mineral and industrial products already named, together with corn, plums, chestnuts, almonds, wax, bacon, cattle, hides, wool, hemp, timber, turnery, oak planks, &c. Cheese also, made of ewe's milk mixed with that of goat's, is manufactured in great quantities in the south of the department, especially in the neighbourhood of Roquefort and forms an important article of export.

These departments of industry are carried on in numerous towns of moderate size. In Rodez, serges, coarse woollens, woollen yarn, and leather, are manufactured. At La Guiolle, a large quantity of good cheese, and some woollen stuffs are made. St. Geniez has several woollen and cotton factories, besides numerous tan-yards, dyeing establishments and naileries, the produce of which, together with timber, wool, and turnery, are the chief articles of trade. At Millau, broad cloths, gloves, and leather of different kinds, are made; there are also some silk-throwing establishments. These products, with wool, hides, timber, oak-staves, cheese, wine, and cattle, are the chief articles of trade. The same products are met with at St. Affrique. Near Roquefort there are extensive grottoes, in which about 18,000 cwts. of cheese are annually made. In Villefranche, the manufacturing industry is important: there are several large linen factories, copper and iron foundries, tan-yards, and paper-mills. At Aubin there are rich coal mines, which produce 500,000 to 600,000 tons per annum; there are also mines of sulphur, alum, and iron, and several large iron furnaces in the neighbourhood.

AVIGNON, the capital of the department of Vaucluse, in France, has been rapidly advancing lately in trade and manufactures. Silk stuffs of various kinds are largely manufactured; of taffeta (florence), about 5,000,000 yards are annually made, the value of which is estimated at upwards of 8,000,000 francs: there are also a cannon foundry, a foundry for sheet-iron, copper, and tin, a saltpetre refinery, tanneries, paper-mills, type-foundries, cotton factories, and various other industrial establishments in the town. Avignon has also a large trade in books, corn, wine, brandy, sumac, colonial products, and cattle. A great part of the trade of Avignon is carried on through the port of Marseille, to and from which goods are conveyed on the Rhone by way of Arles. There is constant communication by steamers with Lyon, Arles, and Marseille, and by diligence with Paris and Marseille several times a day. A railroad now in course of construction between Lyon and Marseille passes through Avignon.

AVILA, a district of Old Castile in Spain, produces grain, fruit, oil, wine, and flax. There are at Avila (the chief town in the district) manufactories of woollen stuffs, cotton prints, and hats, besides the royal manufactory of cloth, the machinery of which is moved by water.

AVOIRDUPOIS, or AVERDUPOIS is the

common system of weights in England, now applied to all goods except the precious metals and medicines. Thus, a pound of tea is a pound *averdupois*, and contains 7000 grains; a pound of gold is a pound *troy*, and contains 5760 grains. The ancient pound was heavier than the averdupois, and weighed 7600 grains. The earliest regulations on the subject fix the *troy* weight.

A cubic foot of water, at 62° Fahrenheit and 30 in. barometrical pressure, weighs 997·14 ounces, which, being very nearly 1000 ounces, gives an expeditious rule for deducing the real weight of a cubic foot of any substance from its specific gravity. For example, if the specific gravity of gold be 19·36, the weight of a cubic foot of gold is 19360 ounces averdupois.

AXIS, AXE. This word is used in so many different senses, that it may be defined as follows: any line whatsoever which it is convenient to distinguish by a specific term, with respect to any motion or other phenomenon, is called the axis. Thus we have axes of coordinates, of oscillation, of inertia, of rotation, of polarization, &c. The word, when used by itself, generally means either *Axis of Rotation*, or *Axis of Symmetry*. An axis of rotation, or revolution, is the line about which a body turns; an axis of symmetry is a line on both sides of which the parts of the body are disposed in the same manner, so that to whatever distance it extends in one direction from the axis, it extends as far in the direction exactly opposite. Or if perpendiculars to the axis be drawn from all points and in all directions through the body, the whole of each perpendicular which is within the limits of the body will be bisected by the axis. Such is the middle line of a cone, any diameter of a sphere, the line drawn through the middle of the opposite faces of a cube, &c.

AXLE. Since the extensive use of locomotives, the theory of the action of axles, and the enquiries into the cause of their fracture, have been the result of elaborate enquiry among engineers. Rowan's patent axles are intended to lessen the ordinary amount of friction, by the use of friction rollers applied in a peculiar way. Mr. Bessemer, in a recent paper on the frequent breakage of the axles of railway carriages, attributes it mainly to the oscillations of the carriage. Whether solid or hollow axles, with a given weight of metal, are the stronger, is a disputed point among engineers; Mr. Yorke, in a paper read before the Institute of Civil Engineers in 1843, contends for the superior strength of hollow axles; but this conclusion is disputed by others.

The theory of axles may, indeed, be considered at present in a tentative state; meanwhile patents are frequently obtained for improvements in form and in mechanical action.

Hardy's patent axles have shown the possession of such a remarkable degree of toughness, that the Privy Council in 1849 granted a continuation of the patent; and remarks were made in the House of Lords relating to the lessening of railway accidents by their use. Since that period the patent has been sold for a considerable sum to a company at Birmingham, established for the manufacture of these axles on a large scale.

AXMINSTER. This Devonshire town was formerly celebrated for its manufacture of carpets. In this it rivalled the productions of Turkey and Persia so successfully, that the carpets of Axminster were considered little inferior to those imported. They were woven in one entire piece. But after lasting for 100 years, this manufactory was given up, the demand not being found equal to the expense of producing the article.

AYLESBURY is chiefly an agricultural town. There is one silk factory; but the lace manufacture which once flourished here has greatly declined. The making of straw-plait is more prosperous; and the straw-plait market established some years back is still (1850) held every Saturday. Many of the inhabitants of the neighbourhood add to their income by their skill in breeding ducks, of which they send a considerable number to the metropolis about Christmas.

The straw-plait of the Aylesbury district will occupy a place in the industrial display of 1851.

AYRSHIRE maintains a goodly rank among the commercial counties of Scotland. The mineral riches are considerable. Coal is abundant, especially in the middle and northern parts of the county. The coal is of different varieties, among which is the blende coal, found in the earth charred, or reduced to the state of a cinder; it burns without smoke or much flame, and is used for drying grain and malt. Considerable quantities are exported to Ireland and to the Western Isles. Near Saltcoats eleven different strata or seams of coal of various quality have been discovered. The proprietor constructed the harbour of Saltcoats, and built salt-pans, in order to use profitably the otherwise useless part of the coal.

The county affords abundance of limestone. Freestone is quarried in great quantity; and there is some whinstone and puddingstone. Mill-stones of coarse granite are quarried at Kilbride, near the northern part of the coast, and are in great request for their hardness and durability; they are exported to the West Indies and to America. Near Auchinleck is a quarry of black stone much used for building ovens, on account of its power of resisting the action of fire. The whetstone known by the name of Water-of-Ayr stone is found near the banks of the river Ayr. Marl also is procured in many places.

Ironstone is also abundant, and at a few places extensive iron works are carried on. Lead, plumbago or black-lead, antimony, and copper (of each of which the quantity is small) may be considered as nearly completing the list of minerals of Ayrshire.

The manufactures of Ayrshire are important, for the district possesses considerable advantages. Fuel is abundant; materials for building are at hand; and channels of communication of all kinds are open in every direction. The vicinity of Glasgow and Paisley seems to have given an impulse to improvement. Carpets, cloths, and stockings are manufactured; and the most improved machinery is in use. The woollen manufacture has long been extended to all parts of the county, and is carried on to a considerable extent by the aid of machinery. Dyers and fullers have established themselves in connection with it. The linen manufacture has never been carried to any great extent. The silk manufacture was tried but did not become permanent. The cotton manufacture, established in Glasgow and Paisley, soon extended itself into Ayrshire. Great cotton works were erected at the village of Catrine on the river Ayr; and the weaving of muslins has been established nearly all over the county. Bleaching, as connected with the cotton trade, has also been extensively carried on. Woollen bonnets and serges are largely made.

Leather is another manufactured article of considerable importance. Tanneries have been greatly extended; the leather is employed in making shoes, boots, and saddlery. Of the latter some is exported to foreign parts. Pottery for domestic purposes is made, but not to any great amount, or with much profit. Kelp, soda, and salt have all been made to advantage along the shore.

A'ZIMUTH. The azimuth of a celestial body is the angle contained between the plane of the meridian of any station and that of a vertical circle passing through the body. The instruments by means of which the azimuth of a celestial body may be directly observed are the theodolite and the altitude and azimuth circle. [CIRCLE; THEODOLITE.] An instrument is said to be moved *in azimuth* when it is turned on a vertical axis, so that any line in it drawn through the axis points to the same altitude in the heavens, but not to the same azimuth.

AZOF, or AZOV, called by the Turks Assak, the once busy town on the shores of the once-important lake of the same name, has fallen to insignificance, chiefly by the shallowing of the water near the shore. Taganrog is the only town on the lake which carries on commerce to any extent.

AZORES. These beautiful islands, which stand so invitingly in the track of ships voyaging down the Atlantic, are very fertile. The lava districts are cultivated with vines, oranges, and lemons; but, where decomposition has afforded richer land, it yields wheat, Indian corn, beans, &c. Both European and tropical fruits arrive at the greatest perfection; and the face of the earth is so diversified as in many places to exhibit within a small extent gardens of aromatic flowers, pastures, vineyards, orangeries, &c. The islands, though still abounding in uncultivated lands, produce much more than sufficient for the supply of their present population, not only of the necessaries but also of the luxuries of life. Vessels touching at any of them are certain of being able to procure an abundant stock of refreshments; and the cattle are equal to any in the world. On the flanks of the mountain called the Peak of Pico are produced the finest wines, which, though inferior to those of Madeira, being much cheaper, find a good market both in Europe and America. The inhabitants of the islands import woollens, hardware, boards, staves, pitch, tar, iron, &c.; in return for which wine and fruit are the chief payments.

AZOTE. English chemists now mostly concur in giving the name of NITROGEN to the gaseous element which used to be called *Azote*.

AZURE BLUE. COBALT.]

B

BAALBEC, or BALBEC, in Syria, is celebrated for three temples and other relics of ancient works of art. The great temple was peripteral, having ten columns in front and nineteen on the flank; the length of the temple is near 290 feet, and the width 160: in its perfect state, the height from the ground to the top of the pediment was 120 feet. The shafts of the columns consist of three pieces, united so exactly, that the blade of a knife cannot be inserted between the joints. The two smaller temples, like other buildings whose ruins are strewed about this once-important city, are mostly of the Corinthian order.

BABLAH, is a name given to the rind of the fruit of the *mimosa cineraica*, brought from the East Indies and Western Africa. It is used as a substitute for more expensive dye-drugs to impart a drab colour to cotton.

BABYLON. This world-renowned city is still, in its ruin and desolation, a place of interest to the artist and the artificer, on account of the huge fragments which it contains. These ruins consist of mounds of earth formed by the decomposition of buildings, channelled and furrowed by the weather; the surface of them is strewed with pieces of brick, bitumen, and pottery.

In the eastern quarter of the city there is one remarkable group of ruins. It forms a mass which is 1100 yards in length and 800 in its greatest breadth; its figure nearly resembles that of a quadrant; its height is irregular; but the most elevated part may be about 50 or 60 feet above the level of the plain, and it has been dug into for the purpose of procuring bricks. Just below the highest part of it is a small dome, in an oblong enclosure, distinguished by the name of Amram Ibn Ali. On the north is a valley of 550 yards in length, the area of which is covered with tussocks of rank grass, and crossed by a line of ruins of very little elevation. To this succeeds another grand heap of ruins, the shape of which is nearly a square of 700 yards' length and breadth, and its south-west angle is connected with the north-west angle of the mound of Amran by a ridge of considerable height and nearly 100 yards in breadth. About 200 yards from this mound is a ravine, hollowed out by those who dig for bricks, in length 100 yards, and 10 feet wide by 40 or 50 deep. On one side of it a few yards of wall remain standing, the face of which is very clean and perfect, and appears to have been the front of some building. A little to the west of the ravine is the Kasr, or palace, a huge mass of brickwork in a surprising state of preservation. A mile to the north of the Kasr is a ruin called the Mujelibè, meaning the *overturned:* its shape is oblong, and its height, as well as the measurements of its sides, irregular. The sides face the cardinal points; the northern is 200, the southern 219, the eastern 182, and the western 186 yards in length; and the elevation of the south-east, or highest angle, is 141 feet. The western face, which is the least elevated, is the most interesting, on account of the appearance of building it presents. Near the summit of it appears a low wall, with interruptions, built of unburnt bricks mixed up with chopped straw or reeds, and cemented with clay-mortar of great thickness, having between every layer a layer of reeds; and on the north side are also some vestiges of a similar construction. The summit is covered with heaps of rubbish, in digging into some of which layers of broken burnt brick cemented with mortar were discovered, and whole bricks with inscriptions are sometimes found. The whole is covered with innumerable fragments of pottery, brick, bitumen, pebbles, vitrified brick or scoria, and even shells, bits of glass and mother-of-pearl. It appears that the walls were lined with a fine burnt brick to conceal the unburnt bricks, of which the body of the building was principally composed. About 70 yards to the north and west of the Mujelibè are traces of a very low mound of earth, which may have formed an inclosure round the whole.

But the most vast ruins are those of the Tower of Belus, or Birs Nimroud. These form a mound of an oblong form, the total circumference of which is 762 yards. At the eastern side it is cloven by a deep furrow, and is not more than 50 or 60 feet high; but at the western side it rises in a conical figure to the elevation of 198 feet, and on its summit is a solid pile of brick, 37 feet high by 28 in breadth. The fine burnt bricks of which it is built have inscriptions on them; and so excellent is the cement, which appears to be lime-mortar, that it is nearly impossible to extract one whole. The other parts of the summit of this hill are occupied by immense fragments of brickwork of no determinate figure, tumbled together and converted into solid vitrified masses, the layers of brick being perfectly discernible. These ruins stand on a prodigious mound, the whole of which is itself a ruin, channelled by the weather, and strewed with fragments of black stone, sandstone, and marble.

Buttresses and pilastres were component parts of Babylonian buildings, which were sometimes decorated with niches; the edifices generally were of bricks, either dried in the sun or burnt in a kiln or furnace. Tiles were also painted and glazed for the purpose of decorating buildings, and a very fine sort of brick was employed to case thick walls built of common bricks or rubbish. These bricks were impressed with characters. The clay of which they were formed appears to have been mixed up with chopped straw or reeds. When baked or dry they were laid in hot bitumen, sometimes in clay-mortar, and sometimes also in a fine lime-mortar. Thick piers were used for columns. Timber was scarce; and the wood-work of the houses, which were sometimes of three and four stories, was made of the date-tree. Round the posts reeds were twisted, on which a coat of paint was laid. The bitumen used in the building of Babylon is not by any means so tenacious as the mortar. Mr. Rich thinks that lime-cement was most generally employed.

In the British Museum there are many specimens of Babylonian bricks. Stones, elegantly engraved, and seal-rings were in general use among the Babylonians. Heeren is of opinion that these stones and the engraved cylinders served for signatures. These cylinders were made not only of clay, but of the hardest stones, and the Babylonians had brought the art of cutting these stones to a very high state of perfection. Heeren mentions a cylinder of jasper, and Sir R. K. Porter another of white agate.

BACON. Every one knows that bacon is pork prepared by a process in which salt, heat, and smoke are employed. Unless of the best kind, it is either prepared from inferior meat, or prepared in a defective manner. Good bacon has a thin rind; the fat has a firm consistency and a reddish tinge; and the lean adheres strongly to the bone.

As there is no excise duty on bacon, there are no means of ascertaining the quantity made in this country. Imported bacon pays a duty of 14*s.* per cwt. from foreign countries, and 3*s.* 6*d.* from the colonies. Our imports of bacon in 1848 amounted to 211,000 cwt. We export a small quantity every year to the colonies and the East Indies.

In a recent Liverpool commercial list, it is stated that the sale of foreign bacon in this country has not been brisk during the year 1850. 'We attribute this to the very plentiful supply and consequent cheapness of both Irish and English bacon. The cure of the former is estimated to have been nearly as great as during any previous season, while that of the latter has been undoubtedly much larger.' The prosperous condition of the working classes in this country enabling them to neglect almost entirely the ordinary and even middling kinds of bacon, the dealers have lately had difficulty to find a market for any but the best.

BACON. Were it possible to trace the services which were rendered to industry, through the medium of science, by Roger Bacon in the 13th century, and by Francis Bacon in the 16th and 17th, the list would doubtless be an important one; but it would belong to the biography of Science rather than of Art. The *Opus Majus* of Roger Bacon laid the groundwork for better reasoning in later ages; but the great points by which Bacon is known are his reputed knowledge of gunpowder and of the telescope. With regard to the former, it is not at all clear that what we call gunpowder is intended, though some detonating mixture, of which saltpetre is an ingredient, is spoken of as commonly known. In respect to the telescope, it must be admitted that Bacon had *conceived* the instrument, though there is no proof that he carried his conception into practice, or *invented* it. The question has been agitated whether the invention of spectacles is due to Bacon, or whether they had been introduced just before he wrote. He certainly describes them, and explains why a plane convex glass magnifies. But he seems to us to speak of them as already in use.

In respect to the far greater Francis Bacon familiarly known as Lord Bacon, the contributions to Art or Industry were more indirect; for his scientific labours applied chiefly to the logic of science, to the best means by which the human mind may master the difficulties which lie at the threshold of all scientific enquiries. He was in fact removed two stages from the philosophy of manufactures: he taught the man of science how to grasp theoretical principles; and the man of science, thus taught, was in a condition to apply his science to the practical wants of the manufacturer, the mechanist, and the engineer.

BADAKHSHAN, one of the khanats of Turkistan, is rich in gems. The celebrated ruby mines of Badakhshân, often alluded to by Persian poets, are situated at a place called Gharan, near Shughnân, near the Oxus. They are at present worked by the command of the chief of Kundûz, who has conquered this part of the country. The rubies are said to be found like round pieces of pebble or flint, and imbedded in limestone.

BADEN. The grand-duchy of Baden is rich in many kinds of produce. Agriculture is the chief occupation of its inhabitants, and yields a surplus of produce for which Switzerland and France afford a ready market. Only six acres in a thousand are said to be waste land. On an average it is stated to produce about 1,358,000 quarters of all descriptions of grain, and exports between 75,000 and 93,000. It yields also hay and other fodder for horses and cattle in superabundance. The upper and lower districts produce rapeseed, hemp, flax, and opium; and the lower districts in particular, which include the former Palatinate of the Rhine, where the best husbandry prevails, considerable quantities of tobacco and hops. Potatoes and fruits are largely grown; and cyder, perry, and wine are made in considerable quantities. The timber trees of the grand-duchy consist principally of the fir, pine, oak, beech, birch, alder, aspen, and ash.

Among the mineral productions we may enumerate the garnet, crystal, jasper, chalcedony, and onyx; marble, alabaster, gypsum, chalk, porcelain earth, and potter's clay. Silver, copper, and lead are found along the valley of the Kinzig and Münster, and in the neighbourhood of Kork and Pforzheim. Iron ore is obtained from the mines at Stockach, Kandern, the Black Forest, Hauenstein, &c. Inconsiderable quantities of Cobalt, manganese, zinc, sulphur, coals, alum, vitriol, and bismuth, are likewise raised. Salt is procured in great abundance in the Black Forest.

The manufacturing industry of the grand-duchy does not rank high, either for its extent, or for the variety or superiority of its productions. Pforzheim, Carlsruhe, and Mannheim are the chief places. The government possesses eight iron-works; and there are others in private hands, but the produce is small. Fire-arms, iron wire, copper ware, nails, alum, vitriol, saltpetre, linen, woollen, cotton, silk, clocks, watches, jewellery, wooden ware, paper, tobacco, potash, white lead, smalt, glass, and earthenware, are manufactured in various parts of the duchy—mostly in small quantities.

The position of the country on the Rhine, Main, Neckar, and other streams, and the access which they give it to Switzerland, France, and Germany, have rendered Baden a country of extensive transit, and secured to it outlets for its own productions. The imports of Baden consist of French and other wines, colonial produce, drugs and dyes, iron, steel, cottons, silks, fine woollens, horses, cattle, &c., and its exports of timber, grain, meal, oil, skins and hides, wine, hemp, linen, tobacco, iron wares, jewellery, fish, &c.

BADGER. The hide of this animal is not without value; when properly dressed, it makes the best pistol furniture. In some parts of France badger's hides are commonly used as a sort of cover or ornament to the collar and trappings of waggon-horses. The hair is used for painter's brushes, and brushes for other purposes. The hind-quarters, when salted and smoked, make excellent hams. In China, as Bell the traveller assures us, dozens of badgers may be seen hanging for sale, as food, in the meat markets of Pekin.

BAGDAD is the name both of a pashalic and of a city, in the Tigris region of Asia. The pashalic produces the tamarisk shrub, the liquorice plant, the willow, the poplar, the castor-oil plant, the carob plant, the crowfoot, the caper, and many others. Grapes, figs, pomegranates, and quinces are largely grown; but the plants best known in England are not much cultivated. The region is not rich either in timber or in minerals.

The city of Bagdad, so famous in oriental story, was formerly a great emporium of eastern commerce. Besides the traffic with its own manufactures, it was the entrepôt for the commodities of eastern and western Asia. But the political and commercial events of recent years have greatly reduced this commerce. The manufactures are not very numerous or extensive. The red and yellow leathers are excellent, and are held in high estimation throughout Turkey. Another principal manufacture consists of pieces of a sort of plush, in shawl patterns, often very rich and beautiful, and used by the Turks for covering the cushions which form their divans or sofas. A few other manufactures in wool and silk are carried on.

BAGPIPE, a musical instrument, which consists of a leathern bag, inflated by a port-vent fixed in it, which has a valve. It has three pipes, the first and second called the great and little drone, each giving but one note, the third, a kind of oboe having eight ventages, or holes, on which the tune is played by the fingers. The wind is communicated to the pipes by compressing the bag under the arm, the mouth-piece of each pipe being fixed in the bag. The compass of this instrument is three octaves.

A similar instrument was in use among the antients under the name of *tibia utricularis.* The bagpipe is mentioned by Chaucer as the music to which the Canterbury pilgrims performed their journey.

BAHAMAS. These West India Islands

are in general fruitful, and produce several species of trees, as mahogany, satinwood, lignum vitæ, cedars, pines, braziletto, wild cinnamon, fustic, and pimento, with a great variety of esculent vegetables. Cattle are reared in great plenty.

The chief articles of export are sugar, cotton, dyewoods, bark, fustic, salt, with turtle and fruits. The crops of cotton are often destroyed by the chenille and red bug; the latter stains the cotton so as to render it of little value. The cultivation of cotton is no longer the staple. Great numbers of pineapples are grown for sale, principally to North American traders. The islands generally produce sufficient maize and ground provisions for the use of the inhabitants. Turk's Islands afford the principal supply of salt; from one to two thousand 'rakers' visit them annually, beginning their operations in February. The Bahamas took British produce and manufactures to the value of 24,709*l.* in 1849.

BAHAR, one of the provinces of Northern India, yields large quantities of saltpetre, which is produced in artificial beds, consisting of the refuse of vegetable and animal matters in a state of decomposition, mixed with calcareous and other earths. Opium is produced very abundantly; but wheat of excellent quality is the chief produce. Rice, sugar, indigo, cotton, castor-oil, and essences, particularly the attar of roses, are among the ordinary productions of the province.

BAHAWU'LPOOR, in the province of Mooltan, is deserving of our notice in this place—not so much for its products as for the commercial energy which marks its inhabitants. The manufactures carried on by them are of silken girdles and turbans, and some species of cotton cloths called coongees, which are celebrated for the fineness of their texture: the weavers are chiefly Hindoos. The merchants of Bahawulpoor are also Hindoos; they have a great deal of commercial enterprise, and deal extensively in goods of European manufacture, which they receive from Pallee in Marwar, by way of Bicaneer and the desert of Ajmeer, and conveyed them by land-carriage through Mooltan and Lahore, crossing the Indus at Kaheree. These Bahawulpoor merchants often travel to Balk and Bokhara, and sometimes to Astrakhan, for commercial purposes.

BAHI'A, one of the maritime provinces of Brazil, is distinguished rather for commerce than for manufactures. The metals, which once formed a considerable portion of the wealth of this province, are now of very little importance. Gold has long ago ceased to be worked: silver is found, but it would not pay the expense of working. Iron is abundant, but neglected. Copper is still worked in the northern district, but not to any great amount. The largest piece of native copper perhaps in the world (excepting one recently found on the shores of Lake Superior) was found about two miles to the east of the town of Cochocira; it weighed 1666 pounds, and is now in the Royal Museum at Lisbon. Armenian bole, antimony, saltpetre, and rock-salt, are among the mineral produce.

The chief cultivated plants are cotton, sugar, coffee, tobacco, and corn; while among the spontaneous products of the soil, possessing commercial value, are ipecacuanha, Jesuits' bark, jalap, tamarinds, Brazil root, curcuma or turmeric, betony, copal, dragon's blood, mastic, copaiba, Brazil-wood, bow-wood, iron-wood, oil-wood, cachew nut, nayha, palm, and numerous timber trees for carpentry and cabinet work.

BAHREIN is the name of a bay and an island on the Arabian coast. The chief town of the island, called Manama, is at the north-east extremity, and is large and populous, being supposed to contain upwards of 40,000 inhabitants. The bazaar is well supplied with cattle, sheep, poultry, fish and vegetables; and a very considerable trade is carried on. Upwards of 140 vessels of various sizes are employed in trading; but the pearl fishery is of the greatest importance to the island, which in the season employs 2,400 boats, each containing from eight to twenty men. The annual produce of these fisheries amounts, it is said, to sixteen or twenty lacs of dollars.

BAIGORRY, a valley in the south of France, has rich copper and iron mines, and large copper and iron works for smelting and refining the ores.

BAIKAL. The mineral productions on the shores of this extensive Asiatic lake are noticed under ALTAI MOUNTAINS.

BAIREUTH, in Bavaria, has tan-yards, manufactories for making tobacco-pipes, parchment, linen, porcelain and earthenware, cottons, and stockings; and the inhabitants carry on considerable trade in grain and flour.

BAKEWELL, is situated in the middle of that part of Derbyshire which is so rich in mineral produce. There are stone and marble quarries at Ashford, and lead mines at some little distance from Bakewell, which afford employment to numerous labourers belonging to the town and its vicinity. The marble, a very beautiful black kind, is wrought here into a great variety of useful and ornamental objects; and the inlaying of it with a species of mosaic is carried on with great skill. Those who are familiar with the contents of the

British Museum will remember two beautiful tables in the Mineralogical Gallery made of Bakewell marble. Near the town is a cotton manufactory established by Arkwright; but during the last ten years it has only been worked occasionally.

In the parish of Bakewell there is one building which will ever be associated with the recollection of Mr. Paxton's Crystal Palace in Hyde Park—we mean *Chatsworth*. The unequalled conservatory which Mr. Paxton constructed for the Duke of Devonshire in the grounds of that palatial residence was the forerunner of the building now being erected for the Exhibition of Industry. This building, and the relation between it and the Hyde Park structure, will be found described a few pages later [CONSERVATORY].

BAKING. [BREAD.]

BAKU. This peninsula, which juts into the west side of the Caspian Sea, is celebrated for its numerous volcanoes, which discharge volumes of mud; but still more for the superabundance of naphtha with which its soil is charged, particularly in the neighbourhood of the capital. It not only issues spontaneously through the surface, but rises wherever a hole is bored. It is of two descriptions, black and white; and its principal sources are situated at a spot called Balegan, about 6 miles from Baku. The whole of these naphtha springs belong to the government, and are farmed at a rental of about 9000*l.*

BALAGHAUTS, a district near the Madras coast of India, exports indigo and cotton in considerable quantities. The central and eastern divisions contain several diamond mines; and it is from these, and not from mines in their own district, that the diamond merchants of Golconda have been supplied.

BALANCE. The instrument most commonly known by the term balance is a superior sort of scales, executed with all the precision necessary for the nicest operations of physics, and particularly of chemistry.

A balance should be so sensible that, when equipoised, a very small additional weight in either scale may overcome the friction and adherence of the pivot by which it rests; and the diminution of friction to the utmost possible extent is accomplished by giving the supports a high polish and attaching a knife-edge pivot to each side of the beam. The knife-edges must not be so sharp as to cut the supports; and, to prevent them from becoming too blunt, they are in some balances removed from the supports, when the instruments are not in use, by an apparatus for the purpose.

The sensibility of a balance is estimated by the angular deviation of the beam from a horizontal position when a very small weight is placed in one scale: thus, if one grain placed in a scale of each of two balances should make the beam of the first incline two degrees, and that of the second four degrees, the latter balance would be twice as sensible as the former. The quantities weighed in delicate balances are usually small. A balance made by Ramsden for the Royal Society, weighing ten pounds altogether, turned with the ten-millionth of that quantity, or with about the thousandth part of a grain.

A balance should be made as much as possible of brass. Steel and iron are apt to acquire magnetic properties. It should also be enclosed in a glass case, with doors for communication.

Mr. Cotton's beautiful apparatus, employed at the Bank for weighing sovereigns, is described under GOLD-WEIGHING MACHINE. The more ordinary balances for commercial purposes are noticed under STEELYARD; WEIGHING MACHINES.

BALASO'RE, a large town, not far from Calcutta, affords an instructive example of the mode in which British manufactures become spread among the islands of the east. The trade carried on here is principally with the Maldives' islanders, whose boats, constructed of the trunks of cocoa-nut trees, arrive at Balasore in the months of June and July, during the south-west monsoon. Their import cargoes consist of coir, cocoa-nut oil, and other products of the cocoa-nut tree, which is their grand staple; cowries, tortoise-shell, and salted fish. These articles they exchange for rice, sugar, broad-cloths, stuffs of silk and cotton, hardwares, and cutlery; and with these they return home during the month of December, favoured by the north-east monsoon. Some trade is likewise carried on in salt, which is made on the sea-shore a few miles from the town, by lixiviating the mud in the manner practised in the Sunderbunds of Bengal.

BALAS RUBY, a term used by lapidaries to designate the rose-red varieties of Spinel. It should be carefully distinguished from oriental ruby (the sapphire), a gem of much greater rarity and value.

BALCONY. Balconies are much employed in edifices of modern date. They are formed nearly on a level with the floors of rooms, and supported on cantilevers or brackets, and sometimes, though more rarely, on columns of wood or stone. The floor of the balcony is laid on the cantilevers, and the sides are enclosed with a rail of iron, or a balustrade of stone. Since the introduction of Grecian architecture some balconies have been inclosed with small Greek columns, instead of the baluster used by the Italian architects. In Venice there are very magnificent balconies in the Gothic taste, remarkable for their richness. Elizabethan architecture shows some very elaborately designed balconies; but perhaps the nearest example to the *palco* of the Italians will be found in some of the colleges of Oxford. Magdalen College contains an example of such a balcony in a pulpit supported on corbels.

BA'LDACHIN, a kind of canopy, either supported on columns, or suspended from and used to cover an altar in a Roman Catholic church. The form, for the most part, is square, and the top covered with cloth with a hanging fringe: sometimes the fringe is formed of pieces of cloth cut out after the fashion of a banner. The baldachin in St. Peter's at Rome, made by Bernini, is the most celebrated, and is the largest known work of the kind in bronze.

BALEA'RIC ISLANDS. These Mediterranean islands, comprising Majorca, Minorca, and three others, yield granite, marble, jasper, porphyry, slate, and pit-coal, also lead and iron. The soil is generally good, and chiefly cultivated with vines, olives, and other fruit-trees: corn is not produced in sufficient quantities for home consumption. This article and cattle form the principal imports, in exchange for wines and brandies of an inferior quality, coarse woollen cloths, and dried fruits; the pottery made in these islands is much esteemed.

BALIZE, or BELIZE. [HONDURAS.]

BALKAN. The natural riches of this extensive Turkish mountain system are very imperfectly known. The silver and gold mines worked by the ancients are not now known. Yet, in some parts, mines of this description are worked, as at Kostendil, or Guistendil, not far from the sources of the Karasa Struma, in the Egrisu Dagh. In the same range, farther to the west, are considerable mines of copper, which are also found in the Emineh Dagh, near Shumla, and probably in other places. Iron seems also to be abundant, and is got from the Dupishna Dagh, near the place which has given to this range its name. In many parts there are mines of lead, and in others rock-salt in great abundance. Marble is abundant in the southern ranges.

BALKH. This once celebrated Asiatic city has sunk into insignificance. Its commerce and manufactures have been superseded by those of Bokhara.

BALLAST, a term used to denote any heavy material placed in a ship's hold with the object of sinking her deeper in the water, and of thereby rendering her capable of carrying sail without danger of being overset. Ships are said to be in ballast when they sail without a cargo, having on board only the stores and other articles requisite for the use of the vessel and crew, as well as of any passengers who may be proceeding with her upon the voyage. In favour of vessels thus circumstanced it is usual to dispense with many formalities at the custom-houses of the ports of departure and entry, and to remit the payment of certain dues and port charges which are levied upon ships having cargoes on board.

A foreign vessel proceeding from a British port may take on board chalk as ballast. Regulations have at various times been made in different ports and countries determining the modes in which ships may be supplied with ballast, and in what manner they may discharge the same; such regulations being necessary to prevent injury to harbours.

Iron weights are sometimes used as ballast, but sand is more extensively employed. All the empty Newcastle coal ships carry river-sand ballast on their return voyages to the north; and the hoisting and shipping of this ballast in the Thames amounts to 10,000 tons per week.

BALLISTIC PENDULUM, a rectangular block of elm weighing from 600 to 2800 lbs., and suspended by an iron stem from a horizontal axle, which rests upon the upper part of a strong frame of timber standing on the ground, or, for the sake of greater stability, inserted in the wall of a building. It is used for determining the velocities of shot discharged from a gun by given quantities of powder. The shot being made to strike the block in the direction of its fibres, and entering it to a certain distance, causes it to vibrate on the horizontal axis of the machine, when, by the extent of the vibrations, measured from a vertical plane passing through the axis, the velocities at the instant of striking are found.

The block is strongly bound by bars of iron, and, in order to obtain the extent of a vibration, a tongue of iron terminating below in a point projects from the lowest surface of the block; and this tongue makes a mark which indicates the extent of the vibration.

By the Ballistic Pendulum has been obtained almost all the information we possess respecting the velocities of cannon balls and the resistance of the air in the case of bodies in rapid motion.

BA'LLIUM. This term antiently meant an outer bulwark; but was afterwards adopted for the area or court-yard contained within one. In towns, the appellation of ballium was given to a work fenced with palisades, and sometimes masonry, covering the suburbs. When there was a double enclosure of walls, the areas between the walls and within the interior wall were styled respectively the outer and inner ballia.

The name Bailey, as the Old Bailey, in London, and the church of St. Peter in the Bailey, in Oxford, seems to have been derived from ballium.

BALLOON. A balloon generally consists of a bag of silk, or other light material, inflated with gas or heated air, so that, being lighter than an equal bulk of common air, it will rise from the earth with sufficient force to lift a car, in which persons may perform an aërial voyage.

The notion of flying or sailing through the air, evidently suggested by the flight of birds, is very ancient; but passing over the early fables or traditions on the subject, we find the first idea of a real balloon suggested by the Jesuit Francis Lana, in a work published in 1670. The actual invention of balloons, however, is of much later date, and is due to Stephen and Joseph de Montgolfier, paper-manufacturers at Annonay, near Lyon. They first tried to confine hydrogen in paper. Failing in this, in consequence of the escape of the gas through the pores of the paper, they succeeded in raising a small balloon by heating and thereby rarefying the air within it. The balloon was made of large pieces of paper 110 feet in circumference, fixed to a frame, the whole weighing about 500 pounds, and containing 22,000 cubic feet (French measure). On the application of fire underneath, the mass gradually unfolded and assumed the form of a large globe, striving at the same time to burst from the arms which held it. At length it rose with great rapidity, and in less than ten minutes was at 1000 toises of elevation. It then described a horizontal line of 7,200 feet, and gradually sank. This balloon contained nothing but heated air, maintained in a state of rarefaction by a fire, the receptacle of which was attached underneath the globe of paper, which had an orifice opening downwards. This occurred in 1783.

Very soon afterwards balloons were made of varnished silk, and small animals were caused to ascend in them, or suspended from them.

In November M. Pilâtre de Rozier made the first aeronautical voyage attempted with a free balloon. The balloon used was a Montgolfier (fire balloon), 70 feet high, and 46 feet in diameter. It ascended from the Château de la Muette, near Passey, gained an elevation of at least 3000 feet, and, after catching fire, which was easily extinguished by the intrepid voyagers, descended safely, after a journey of 5000 toises (about 6 miles), which was performed in from twenty to twenty-five minutes. On the 1st of December M. Charles ascended to the height of 1500 toises (nearly 2 miles), in a hydrogen balloon of 26 feet diameter, from the Tuileries; and on the 19th of January seven persons ascended in a Montgolfier 126 feet high, and 102 feet in diameter. To reduce the above measures, which are French, to the English standard, it should be remembered that the French foot was equal to 12.7892 English inches.

On the 22nd of February, 1784, a small balloon, launched by itself from Sandwich, crossed the Channel; and in the course of that year several personal ascents were made with both kinds of balloon. M. Blanchard, in his first ascent from Paris on the 2nd of March, with a hydrogen balloon, added wings and a rudder, but found them useless. He also first attached a parachute, or open umbrella, above the car, to break his fall in case of becoming accidentally separated from the balloon. In one of the French ascents of this year the use of oars was tried, with, it was thought, some effect. In England a hydrogen balloon of 10 feet in diameter was launched from the Artillery Ground, London, by Count Zambeccari, on the 25th of November, 1783; but the first personal ascent was made by Vincentio Lunardi, from the same place, on the 15th of September, 1784. On the 7th of January, 1785, M. Blanchard and Dr. Jeffries crossed the Channel from Dover; and on the 15th of June following M. Pilâtre de Rozier and M. Romain ascended from Boulogne with the same object, with a Montgolfier, which caught fire, and precipitated them from a height of 1000 yards. Among the more memorable subsequent ascents may be mentioned that of M. Garnerin in 1802, from London, on which occasion he descended successfully by means of a parachute; that of the same person from Paris, in 1807, in which, after encountering great risks, he landed at, or rather was dashed against, Mount Tonnerre, at a distance of 300 miles from his starting-point; that of MM. Gay Lussac and Biot, from Paris, in 1804, to the height of 13,000 feet, for the purpose of making scientific observations; the subsequent ascent of M. Gay Lussac alone, in the same year, to the height of 23,000 feet; and the attempt made in 1806, by Carlo Brioschi, astronomer royal at Naples, and Signor

Andreani, to attain a yet greater elevation; when they reached an atmosphere so rarefied that the balloon burst, its remains proving, however, sufficient to break their fall so that their lives were saved.

Although much has been suggested, very little has been accomplished towards rendering balloons available for any practical use. Little has been done towards guiding a balloon. Many of the schemes which have been proposed for the purpose evince a singular disregard of the essential difference between a ship and a balloon. The former sails in two fluids of very different density, and the action of the water, the denser of the two, upon the rudder is a guide to the impelling power derived from the air, or lighter or less dense element; but no such regulator can be applied to the balloon, which is sustained, as well as impelled, by the air.

Mr. Green has been the most successful of our æronauts. He was the first to introduce the use of common coal gas instead of hydrogen gas for the purpose of inflation, by which an immense saving of cost is effected, and the buoyancy of the balloon may be longer maintained, as it is far less liable to escape. Mr. Green, accompanied by Messrs. Holland and Monck Mason, made the remarkable voyage undertaken on the 7th of November, 1836, with the Great Nassau balloon. Intending to cross over to the continent, these voyagers started from Vauxhall Gardens, London, at half-past one on the above-named day, crossed the Channel, continued their voyage through the night, and descended at half-past seven the following morning in the valley of Elbern, about two leagues from Weilburg, in the duchy of Nassau. The balloon with which this feat was performed is of silk, more than 60 feet high, and about 50 feet in diameter, and will contain, when fully distended, more than 85,000 cubic feet of gas.

We can hardly avoid an expression of regret that so much ingenuity should be still unprofitably wasted on ballooning. Year after year contrivances are brought forward which have before been shown to be unsound in theory. In 1840 Messrs. Marsh and Ranwell suggested a complicated machine, consisting of a light metallic frame, to which about twenty small balloons were attached. Sir George Cayley has proposed a light kind of frame, exposing about 500 square feet of surface, to which some sort of steering apparatus is to be attached. Mr. Partridge has drawn attention to a machine which had somewhat the appearance of an ovoid balloon; with a complicated apparatus of sails and vanes; and a steam engine fed with liquid fuel! M. Eubriot, in 1839, made an oblong balloon, with a car provided with sails; he expected that the car and sails would guide the balloon; but when the machine was tried at Paris, the balloon guided the car, as it is the wont of balloons to do. Mr. Green himself, in 1840, exhibited a model at the Polytechnic Institution, of an apparatus which he expected would suffice to guide a balloon; but we may conclude that nothing satisfactory has resulted. About ten years ago, Dr. Polli, of Milan, suggested that the structure of a fish should form a model for an aerial locomotive; but he was forestalled in this obvious but fallacious idea, by other parties in England. In 1842 Mr. Henson took out his patent for that "aerial machine" which lived its little day of popularity, and then went out of sight; a small steam-engine, in a car, was to propel a light framework 150 feet long; and a tail 50 feet long was to serve as a rudder at one end; but whether the machine could raise itself to a height, or could propel itself by the engine, or could steer itself by the tail, were enquiries never satisfactorily answered. Next came M. Monge's copper balloon, constructed at Paris in 1844; it was about 30 feet diameter, formed of sheet copper $\frac{1}{200}$th of an inch thick, weighed 300 lbs., and was capable of containing 100 lb. of hydrogen; but of its success we have heard nothing. The egg-shape, the fish-shape, the fan-shape, the kite-shape, all have been proposed, time after time, within the last few years; one of the latest being that of Mr. Bell, who recently patented two machines —a *balloon motor*, having both a sustaining and a propelling power; and a *parachute motor*, having a propelling power which constituted its own sustaining power. The plan looked ingenious upon paper, but this is not very high praise.

Occasionally balloons are made subsidiary to science; but very seldom. The British Association has more than once directed its attention to this matter, but with very little result. In 1843 Mr. Green made observations with meteorological instruments, at five different elevations, varying from 2591 to 6758 feet; while Mr. Jones, the instrument maker, was making similar observations at the surface of the earth at the same time—such observations as these might perhaps be multiplied with advantage. Mr. Rush communicated to the British Association, in 1849, a series of thermometrical and barometrical observations, made during five balloon ascents, in 1847-8-9, at various altitudes ranging up to 20,000 feet. One of the latest suggestions, for making balloons useful, was that recently made by the unfortunate Lieutenant Gale, for rendering assistance in the search of Sir John Franklin.

During the recent ballooning season, it was stated that the number of recorded ascents exceeds 3000, of which the elder Green has made nearly 500; and that the ascertained fatal accidents do not amount to 20.

Of the sad foolery of ascending on the backs of horses, ponies, and other animals, nothing can be said but in condemnation. The last example was that in which Madame Poitevin, decked in white muslin and purple velvet, with a crown of roses on her head, ascended from the Champ de Mars on the back of a *bullock!*

BALSAMODE'NDRON, a genus of Oriental trees, is deserving of our notice here as producing *Myrrh*, and *Balsam of Gilead.* Myrrh exudes from the bark, and is at first soft, oily, and of a yellowish-white colour, then acquires the consistence of butter, and by exposure to the air becomes harder, and changes to a reddish hue. As met with in commerce, it is of two kinds, that which is called *myrrh in tears*, and that called *myrrh in sorts.* The smell is peculiar and rather disagreeable, the taste is bitter and very unpleasant.

The alcoholic tincture of the best myrrh, mixed with equal parts of nitric acid, becomes red or violet. The tincture of the false myrrh (of Bonastre) so treated becomes turbid and yellow, but not red. The taste of this false myrrh is very bitter, but the smell is that of turpentine.

The produce of the *Balsamodendron Gileadense*, though called a balsam, and denominated Balsam of Mecca and Balsam of Gilead, is not entitled chemically to rank as such, being an oleo-resin. It is of two kinds, that obtained by spontaneous exudation, and that which is obtained by boiling the branches. The former is so highly prized in the East and so expensive, that it is never brought to Europe. It is said that even in Constantinople there are only two shops whence it can be procured genuine, and where it costs about 1s. per grain English. That which is obtained by boiling is of different qualities and value, according as the boiling is continued for a short or long time. When for a short time only, the substance which floats on the surface is highly esteemed, and almost all of this quality is consumed in Asiatic Turkey and Egypt. The variety procured by long-continued boiling is sent to Europe in small conical leaden bottles, the mouth of which is closed with a leaden stopper, and covered over with bladder. It is, however, frequently adulterated on account of its high price; and the cheaper kinds ordinarily sold contain not an atom of the real balsam.

BALSAMS. The substances commonly included under this title are of various natures. There are natural balsams exuding from trees, as those of Peru and Tolu, &c., which contain benzoic acid and resin. There are also the balsams of Copaiba, Gilead, &c., which contain no benzoic acid, but are turpentines containing a volatile oil and resin. There were in former pharmacopœias sundry very different preparations ranked together as balsams, such as balsam of sulphur, traumatic balsam, &c.: these, when retained in modern pharmacopœias, are arranged under other forms.

Balsams are obtained from certain vegetables, chiefly of the *Leguminosæ*, or pea tribe, the *Styraceæ*, or Storax tribe, and that section of *Amentaceæ* called *Salicineæ.* Numerous substances of a resinous nature were formerly designated *balsams*, and turpentines and balsams are still popularly confounded with each other. The term balsam, however, should be limited to such articles as contain *benzoic acid* along with a volatile oil and resin. The others, which contain only volatile oil and resin, should be called turpentines, or oleo-resins. The true balsams appear to be only five, viz. balsam of Peru and balsam of Tolu, benzoin, storax, and liquidamber.

Balsams command very varied prices in the wholesale market, from 1*s.* to 6*s.* per lb.

BALTIC SEA. The countries surrounding this very important sea supply timber, grain of different kinds, hides, tallow, &c., in the greatest abundance and of the first quality. If we except the seas contiguous to the British islands, and that which incloses the maritime tracts of the Chinese empire, no portion of the ocean is so much frequented by ships as the Baltic; and this in spite of the difficulties of the navigation. From 13,000 to 15,000 ships enter and leave the Baltic every year, of which about one-fourth are British. It is thought that 2 per cent. of the vessels which visit the Baltic are annually lost, while the commerce between Great Britain and America is carried on with the loss of 1 per cent. Besides this, the harbours of the Baltic are shut up for three or four months by the ice, and thus the navigation is interrupted for nearly one-third of the year. Another disadvantage is the shallowness of the harbours on the southern coast, and the complete want of tides. These difficulties render it necessary that the vessels employed in the Baltic trade should be of comparatively small burthen, averaging from 200 to 300 tons.

BALTIMORE. This important American city has great trade. The exports consist principally of tobacco, wheat, wheat-flour, maize, hemp, and flax; and its imports, of colonial produce and the principal European products and manufactures. Its export trade has of late years been greatly increased by the railroads which connect the town with Philadelphia, Washington, Ohio, York in Pennsylvania, &c.; by these the products of the interior, including even the valley of the Mississippi, find a rapid transit to Baltimore, whence they are shipped to various parts of the United States and of Europe. There are lines of steam-packets to Philadelphia and to Norfolk, and other packets to New York and various parts of the Atlantic. The water power of the Jones' Falls and of the Patapsco, which has a fall of 800 feet in a course of 30 miles, is made available in the numerous flour mills, cotton factories, and other manufactories of cloth, paper, iron, copper, glass, steam-engines, tobacco, chemicals, powder, &c., in the environs of the city. In the city itself there are cotton factories, tanneries, distilleries, breweries, sugar refineries, potteries, saw-mills, glass-works, rope-walks, tobacco manufactories, printing-offices, &c.

BALUSTER, or BALLISTER, a peculiar kind of column employed in balustrades. The baluster has also of late years been formed after the model of Greek and Roman columns. Balusters are placed on a plinth, and are surmounted with a cornice.

BALUSTRADE, the termination of a modern edifice. Balustrades are most commonly placed over the cornices of large edifices, after the manner of a parapet, as at the Banqueting House at Whitehall, and St. Paul's Cathedral. Balustrades are not only employed in large edifices, above the orders of architecture, but also to inclose stairs, terraces, altars, fonts, and the balconies of houses. The balusters forming a balustrade are placed on a plinth, at equal distances from one another, with a small opening between them: they support a cornice, and are divided at intervals by a pedestal.

BAMBARRA. The chief mineral wealth of this African region is iron: it abounds in many districts, and the inhabitauts make utensils of this metal, which are exported to the neighbouring nations. Gold is also found. Salt is imported in large quantitities from the Sahara and the coasts of Guinea. Dried fish is a considerable article of commerce.

Bambarra carries on a very active commerce though it is limited to a small number of commodities. The principal trading places are Jennée, Sansanding, Sego, Yamina, Bammaku, and Boure, all of which are on the Joliba. The last, which lies to the south-west of Bammaku, is the principal market for gold. Besides gold, the principal articles of exchange are slaves, ivory, and coarse cotton cloth made by the natives; they are exchanged for salt brought from the desert, for tobacco, and European merchandise. In their way to the northern countries they pass through Timbuctu, which is the general dépôt for them. There seems also to exist some trade with the coast of Guinea, from which salt is imported.

BAMBERG, in Bavaria, has many points of interest as a commercial town. Among the numerous incorporations in this town is that of the gardeners, which consists of 508 masters, 70 apprentices, and upwards of 250 workmen. The highest prize which it gives —and it is given but once in three years—is for the cultivation of officinal plants, particularly the liquorice root, of which above 50,000 lbs. are annually exported. Very considerable quantities of vegetable seeds are raised and exported by the Bamberg growers. There are sixty brewers here, whose beer is in much demand in some of the German states. The other manufactures consist of tobacco, porcelain, musical instruments, marble wares, starch, sealing-wax, gold and silver plate, gloves, &c. Two annual fairs give life to the trade of the town, the situation of which enables it to share largely in the traffic of central Germany.

BAMBOO, or BAMBUSA. This very useful genus of grass is distinguished by its *stems*, which are hard externally and coated with flint; in the inside they are hollow, except at the nodes, where strong partitions stretch across the inside, and cut off the interior into a number of closed up cylinders.

The purposes to which different species of bamboo are applied are so numerous, that it would be difficult to point out an object in which strength and elasticity are requisite, and for which lightness is no objection, to which the stems are not adapted in the countries where they grow. The young shoots of some species are cut when tender, and eaten like asparagus. The full grown stems, while green, form elegant cases, exhaling a perpetual moisture, and capable of transporting fresh flowers for hundreds of miles: when ripe and hard, they are converted into bows, arrows, and quivers, lance-shafts, the masts of vessels, bed-posts, walking-sticks, the poles of palanquins, the floors and supporters of rustic bridges, and a variety of similar purposes. In a growing state the spiny kinds are formed into stockades, which are impenetrable to any but regular infantry, aided by artillery. By notching their sides, the Malays make wonderfully light scaling-ladders which can be conveyed with facility where heavier machines could not be transported. Bruised and crushed in water, the leaves and stems form Chinese paper, the finer qualities of which are improved by a mixture of raw cotton and by more careful pounding. The leaves of a small species are the material used by the Chinese for the lining of their tea chests. Cut into lengths and the partitions knocked out, they form durable water-pipes, or, by a little contrivance, are made into excellent cases for holding rolls of papers. Slit into strips, they afford a most durable material for weaving into mats, baskets, window-blinds, and even the sails of boats. Finally, the larger and thicker truncheons are exquisitely carved by the Chinese into beautiful ornaments. It is however more especially for building purposes that the bamboo is important. In Sumatra the frame-work of the houses of the natives is chiefly composed of this material. In the floorings, whole stems, four or five inches in diameter, are laid close to each other, and across these laths of split bamboo about an inch wide, are fastened down with filaments of the rattan-cane. The sides of the houses are closed in with the bamboo opened and rendered flat by splitting or notching the circular joints on the outside, chipping away the corresponding divisions within, and laying it in the sun to dry, pressed down with weights. Whole bamboos often form the upupright timbers, and the house is generally roofed in with a thatch of narrow split bamboos, six feet long, placed in regular layers, each reaching within two feet of the extremity of that beneath it, by which a treble covering is formed. Another and most ingenious roof is also formed by cutting large straight bamboos of sufficient length to reach from the ridge to the eaves, then splitting them exactly in two, knocking out the partitions, and arranging them in close order with the hollow or inner sides uppermost; after which a second layer, with the outer or convex sides up, is placed upon the other in such a manner that each of the convex falls into the two contiguous concave pieces, covering their edges; the latter serving as gutters to carry off the rain that falls upon the upper or convex layer.

BAMBOUK, in Northern Africa, is a country which yields silver and iron of excellent quality, and also a great quantity of gold. The principal gold mines of Bambouk are situated to the south of the city of Bambouk, in the mountains of Tambaoura; but a greater quantity seems to be obtained by washing the sand which the rivers have carried down from the mountains and imbedded along their courses in the alluvial soil.

Part of the gold is converted into ornaments for the women. When a lady of consequence is in full dress, her gold ornaments may be worth altogether from 50*l.* to 80*l.* sterling. But the greater part of this metal is annually carried away by the Moors, who take it to Timbuctu, whence it finds its way to the northern coast of Africa, to Egypt, and to Asia. It is exchanged for other commodities, but chiefly for salt, the value of which article is very great in these mountainous countries of Africa. One slab, about two feet and a half in length, fourteen inches in breadth, and two inches in thickness, will sometimes sell for 2*l.* 10*s.* sterling; and from 1*l.* 15*s.* to 2*l.* may be considered as the common price. This salt is brought from the Desert of Sahara. The European merchandise brought from the coast, has till lately been generally paid for with slaves.

BANBURY, in Oxfordshire, has long been noted as a thriving place of trade. The neighbourhood is very thickly covered with villages. The trade chiefly depends on the agricultural neighbourhood; but there is a considerable manufacture of plush, shag, and girth and other webbing, carried on at Banbury, which employs within the parish above a hundred men, besides women and children, in some branches of the manufacture; and many others are engaged in the same manufacture in some of the adjacent villages. A manufacture of linen-weaving, formerly carried on at Banbury, has been abandoned. There is also a manufactory of agricultural implements.

The Banbury Cakes, which have been celebrated from the time of Ben Jonson, are still in high repute; and are not only sold in the town and neighbourhood but sent to considerable distances. They have been exported to America, Australia, and India. The Banbury cheese, which Shakspere and Burton mention, is believed to be no longer made; though a peculiar kind of rich cream cheese is still made in the neighbourhood of Banbury at a late season of the year, whence it is known as 'latter made cheese,' and fetches a high price.

Banbury agricultural implements, and Banbury cakes are to take part in the Exhibition of Industry in 1851.

BANCA, an island in the Indian Ocean lying off the north coast of Sumatra, derives all its importance in a commercial point of view, from its tin-mines, which were first discovered in 1710 or 1711, and have since yielded immense quantities of ore: they appear in fact to be inexhaustible. The ore (an oxide), after being washed in the nearest mountain stream, is smelted, and yields in various proportions from thirty to seventy pounds of tin, for every hundred pounds of ore; the more usual proportion is about sixty of metal to one hundred of ore. If the ore should yield less than twenty-five per cent. of metal, the mine is abandoned as unprofitable. The proportion of metal partly depends upon the quality of the charcoal used in smelting.

From the time of their first discovery, the tin-mines of Banca have been worked by Chinese, whose numbers have been annually recruited. The quantity of tin procured was about 3,000,000 lbs. annually, at the time of cession to the Dutch; since which time it has largely increased; so largely, indeed, that after fully supplying the markets of China and India, a large quantity is annually brought to Europe, where it has consequently lessened the demand for the tin of Cornwall.

BAND, in architecture, a flat moulding, with a vertical face slightly projecting beyond the vertical or curved face of any moulding or parts of an edifice to which it is attached. It is very extensively employed, and is used to give an appearance of binding parts of buildings together.

BANDA ISLANDS, a small group of islands in the Malay Archipelago. These islands produce the nutmeg almost exclusively, whence they are frequently called the Nutmeg Islands, in contradistinction to the Amboynas, which yield the clove.

BANDANAS, or BANDANNAS, a name originally applied to a peculiar kind of silk handkerchief made by the Hindoos, is now given to silk and cotton handkerchiefs manufactured in this country, decorated with patterns of similar character, though by a very different process. A bandana handkerchief has a dyed ground, usually of a bright red or blue, ornamented with circular, lozenge-shaped, or other simple figures, either white, or in some cases of a yellow colour. These spots are said to be produced, in real Indian bandanas, by tying up the parts intended to be white or yellow with bits of thread before exposing the handkerchief to the action of the dye, and thus protecting them from it. In the process followed by British manufacturers, which was invented in 1810 by M. Köchlin of Mühlhausen, the whole surface of the handkerchief is dyed of one uniform colour; a number of pieces thus dyed are laid between two leaden plates perforated with holes wherever white spots are intended to be, and while the several thicknesses of cloth are compressed in this manner by the power of a hydraulic press, a fluid capable of discharging the dye is made to percolate through the holes in the leaden plates, removing, in its passage, the dye from such parts of the cloth as are exposed to its action. By varying the discharging fluid the spots may be made yellow instead of white; and arrangements are sometimes made for combining white and yellow spots in the same handkerchief.

Messrs. Monteith's Bandanna Works, near Glasgow, are among the finest of our factory establishments.

BANGALORE, in the Mysore territory, is a busy commercial place. Its merchants carry on dealings with every part of the south of India. The principal articles which enter into this commerce are salt, sugar, betel-nut, spices, metals, dyeing-stuffs, raw silk, and cotton wool. Many of these articles are imported for the use of its manufacturers. The tissues woven here, both of silk and cotton, are almost entirely retained for the use of the district. The spinning of cotton is all performed by women, who carry their yarn to a weekly market for sale to the weavers.

BANGKOK, the capital of the kingdom of Siam, is a place of considerable trade. The most active commerce is carried on with the ports of the Chinese empire; but the trade between Singapore and other places of the neighbourhood has greatly increased of late years. The internal commerce with the extensive countries drained by the river Menam is also very important.

BANGOR. This Welsh city owes its trade almost entirely to slates, which are brought to Port Penrhyn from the quarries of Llandegai, a place about 8 miles distant, by means of a railway made for the purpose. These quarries give constant employment to upwards of 2000 workmen, and they produce a large revenue to the proprietor. It is stated by Mr. Parry, 'Cambrian Mirror,' p. 152, that '90 years ago these quarries brought only 80*l*. a year to the pocket of the proprietor; and now it is said that the present honourable and fortunate possessor receives the enormous and almost incredible sum of 250,000*l*. a year.' But this no doubt means the produce of the quarries, from which all working expenses have to be deducted. The greater part of the slates are exported, but many are manufactured in Bangor into billiard tables, chimney-piers, and a great variety of objects. One slate manufactory is on a very extensive scale, and there are several less extensive. All of them have been established within a few years; indeed the application of slate to these purposes is quite recent. In addition to the dock and wharfs at Port Penryhn, a new shipping place has just been erected at Garth for shipping slates from another quarry.

BANISTER. [BALUSTER.]

BANJARMASSIN, a town on the south coast of the island of Borneo, carries on a considerable trade with China. The imports of the town are principally of piece goods, cutlery, opium, gunpowder, and fire-arms. The produce exported in return consists of pepper, diamonds, gold dust, wax, camphor, spices, rattans, and edible birds' nests. Some steel of very superior quality is also manufactured at this place.

BANK — BANKER — BANKING. Important as the principle of banking is to the development of manufactures and commerce, it would be impossible so to treat the subject as to bring it within the limits of the present work. There is, however, one aspect of the subject, of much moment to the operative classes, treated under SAVINGS BANKS.

BANK NOTE MACHINERY. Considerble mechanical ingenuity has been shewn in devising the best mode of manufacturing bank notes, so that they shall be light, durable, and not easily imitated by forgers. The making of the paper, the engraving of the steel-plate, and the numbering of the notes, have all called forth this ingenuity.

It was stated some short time ago in the public journals that many of the banks in the United States have adopted the use of a peculiar kind of paper made expressly for bank-notes. There are introduced into the body of the piece of paper for each note as many cotton threads as will shew the value of the note in dollars, up to certain limits; or at least, that a definite number of threads shall represent a definite value in the note; so that no chemical or mechanical tampering with the printed part of the note will prevent the paper from revealing the true original value.

In respect to the plates from which bank-notes are printed, they used to be formed of copper; but as this material soon wears away, a mode of using steel plates was devised by Messrs. Perkins and Heath, by which a surprising number of copies may be taken. A block or thick plate of steel is softened on the upper side; the device is engraved on this softened surface; the block is hardened by a very careful process after the engraving; the device is transferred from the hardened block to the convex surface of a small soft steel roller, by intense pressure; the roller is hardened, and the device is transferred from it to any number of softened steel plates; these plates are hardened after the transfer, and are then in a state to be printed from. By this beautiful train of operations one originally engraved block is made to suffice for an almost endless number of printings.

The mode in which the writing, the emblems, and the ornaments are combined in a bank-note, is so planned as to render forgery difficult. The *numbering* is a remarkable process, as now performed. In 1809, the bank adopted a numbering press invented by Mr. Bramah, by which the expense and uncertainty of finishing annually a large number of bank notes with a pen was materially diminished, and forgery rendered more difficult. The machine was, however, so far incomplete that it produced only units, the tens and hundreds requiring to be brought forward by hand. In 1813 a machine invented by Mr. John Oldham, and used at the Bank of Ireland, had the additional power of effecting numerical progression, from 1 to 100,000 by its own operation; one of these machines was subsequently attached to each press for printing the body of the notes, in order to register and check the number of notes passing through the press.

In 1819 Mr. Bryan Donkin invented a counting machine, applicable to the numbering of notes. Like most others of the kind, its action depended on the relative motion of a series of ratchet wheels with projecting rims, having notches cut in them; so that when the first wheel counted units, the second wheel indicated tens, and so on progressively. When Mr. Thomas Oldham succeeded his father, Mr. John Oldham, as engineer to the Bank of England, he endeavoured to improve on the instruments previously constructed, and devised the form of apparatus now employed, which is as follows:—Four wheels each divided by ten notches, leaving a facet between each pair, engraved with consecutive numbers from 1 to 0, are placed upon a shaft; a portion of their breadth being turned down about one-half of their depth, having a boss or collar between every two. Upon these bosses, and filling up the spaces, rest latches; and over each wheel is a pall, the width of the first being equal to that of the unit wheel, and the breadth of the others equalling that of the wheel and latch. The palls are driven by a crank; by each revolution of which the first wheel is moved through a space equal to one tenth of its entire circumference, bringing regularly forward the numbers from 1 to 0. When the figure 0 is reached, the latch of the second wheel is depressed, and the wheel moves forward one division marking the tens. The same process is repeated with regard to the other wheels, and thus any amount of numbers can be registered, by simply increasing the number of wheels in proportion. Machines of this kind are extensively adopted in the Bank of England; with, of course, an inking apparatus to apply to the types.

A patent was taken out in 1844 for a mode of printing bank-notes intended to obviate the liability to forgery. The surface is covered with two designs, one geometrically regular, and the other very irregular; the two designs are engraved on different plates, and are printed with different inks, the one with visible and the other with invisible ink. Both of the inks are delible or removeable by chemical means; and the usual engraving of a bank-note is printed on paper so prepared. The rationale of the suggestion is this: that whatever means a forger might take to alter by chemical agency the letters or figures, or to transfer them by lithographic or anastatic processes, the state of the paper would betray him: for he would remove some parts of the design in the one case, and fail to transfer it in the other.

BANKS, SIR JOSEPH, was a great contributor to industry and science in the latter half of the last century. Besides his own voyages and travels, all the voyages of discovery which were made under the auspices of Government for the last thirty years of Sir Joseph Banks's life had either been suggested by him, or had received his approbation and support. In the affairs of the Board of Trade, of the Board of Agriculture, and of the Mint, he was constantly consulted, and he took a leading part in the management of the Royal Gardens at Kew. He was a distinguished promoter also of the interests of the Horticultural Society founded in 1804. His influence was frequently directed to soften to men of science the inconveniences of the long war which followed the French Revolution; to alleviate their sufferings in captivity; or to procure the restoration of their papers and collections when taken by an enemy. Baron Cuvier, in his 'Eloge' upon Sir Joseph Banks, mentions that no less than ten times collections addressed to the Jardin du Roi at Paris, and captured by the English, were restored, by his intercession, to their original destination. His purse was always open to promote the cause of science, and his library of natural history always accessible to those who desired to consult it. During the two-and-forty years in which he continued President of the Royal Society, he was indefatigable as an official trustee in the management of the British Museum; to which institution, after innumerable gifts, he made a contingent bequest of his scientific library, together with his foreign correspondence, where both are now deposited.

BANNER, a piece of drapery attached to the upper part of a pole or staff, generally hanging loose, but sometimes fixed in a slight framework of wood.

BANQUETTE, in fortification, is a step formed of earth at the foot of the interior slope of a parapet, and extending along its whole length, except where intervals are left for placing artillery to fire through the embrazures.

BANYAN-TREE, or *ficus indicus* is a native of most parts of India, both on the islands and the main land. The wood is light, white, porous, and of no value. Brahmins use the leaves as plates to eat off; birdlime is manufactured from the tenacious milky juice. The branches spread to a great extent, dropping their roots here and there, which as soon as they reach the ground rapidly increase in size till they become as large as and similar to the parent trunk, by which means the quantity of ground they cover is almost incredible. Roxburgh says that he has seen such trees full five hundred yards round the circumference of the branches, and a hundred feet high, the principal trunk being more than twenty-five feet to the branches, and eight or nine feet in diameter.

BAPTISTERY, an ancient building, in which Christians performed the ceremony of baptism. The most celebrated existing baptisteries are those of Rome, Florence, and Pisa; the most ancient is the baptistery of S. Giovanni in Fonte, near the church of S. Giovanni Laterano at Rome, commonly said to have been erected by Constantine the Great. The plan of this building is an octagon, with a small portico at the entrance; the interior is decorated with eight most beautiful porphyry columns, the finest of the kind in Rome. The diameter of this structure is about 75 feet.

The Baptistery of Florence, which is octangular, with a diameter of about 100 feet, stands opposite to the principal entrance of the Cathedral. The three great bronze doors are celebrated for the beauty of their bas-reliefs, and for the marble and bronze figures above them.

The Baptistery of Pisa, erected between the years 1152 and 1160, by Diotisalvi, is a singular design. The plan is circular, with a diameter of 116 feet; the building is raised on three steps, and surmounted with a dome in the shape of a pear. The external elevation is divided into three stories.

BAR-LE-DUC, is a busy town in the eastern part of France. Its manufactures consist of cotton and woollen goods, cotton yarn, hosiery, handkerchiefs, and leather. The town is celebrated for its sweetmeats, and contains several breweries. The Ornain is navigable below Bar, which has thus a ready means of transit for its industrial products, and for the other items of its trade, namely, wine, iron, fir and oak planks, and firewood for the supply of Paris. There are extensive iron-works and stone-quarries in the neighbourhood.

BA'RBACAN, or BARBICAN, in ancient fortification, was usually a small round tower for the station of an advanced guard, placed just before the outward gate of the castle-yard, or ballium. In cities or towns the barbacan was a watch-tower, placed at some important point of the circumvallation. It had sometimes a ditch and drawbridge of its own. The street of London called Barbican received its appellation from its vicinity to a tower of this sort attached to the city wall, the remains of which were visible within the last half-century.

BARBADOES is one of our West India Sugar Islands. Like others of the same group which have lost a monopoly, it has suffered from the recent change in the sugar duties. There are about 106,000 acres of surface, of which 20,000 were under sugar cultivation in 1848. The sugar exported in that year was about 33,000 hogsheads, and the molasses 13,000 hogsheads. The shipping that belonged to Barbadoes in 1848 amounted to 43 vessels, of 1716 tons, with 255 men. The entire imports for that year were valued at 430,000*l.* and the exports 600,000*l.* In 1849 the island imported British and Irish produce and manufactures to the value of 319,958*l.*

Governor Colebrooke, in a letter to Earl Grey in the spring of 1850, expressed an intention to encourage by every means in his power the cultivation of cotton in Barbadoes. He stated that 'at a former period, and especially in seasons when the sugar crops had failed, or were unproductive, cotton was extensively cultivated.'

BA'RBARY. The products and industry of this great African region are briefly noticed under the names of the countries which comprise it. [ALGIERS; MAROCCO; TRIPOLI; TUNIS.]

BARBERINI VASE. [PORTLAND VASE.]

BARCELONA is the most important manufacturing and trading town in Spain. The staple manufactures are cotton and silk. The commerce of Barcelona, owing to a variety of causes, but principally to oppressive restrictions on the importation of foreign goods, to the independence of South American states, and to the civil wars, has greatly fallen off from its former prosperity. The imports are cotton, sugar, coffee, cocoa, indigo, and other colonial products, chiefly from Cuba and Puerto Rico, hemp, coals, corn, deals, salt fish, hides, iron, hardware, &c. The trade with the Levant, the colonies, and France, as well as the coasting trade, is pretty active. The exports are wrought silks, soap, fire-arms, paper, hats, ribands, wine, brandy, oil, vermicelli, cork, bark, fruits, &c. The so-called Barcelona nuts are shipped to England from Tarragona. The exports and imports of Barcelona each amount to three to four millions sterling annually. From the 'Mercado,' or Price Current, of Barcelona, we are enabled to give the quantities of the principal imports into Barcelona for the year 1846. They are as follows:—8,000,000 lbs. of sugar, 115,000 cwts. of salt fish, 114,000 hides, 3,250,000 lbs. of cocoa, 2,000,000 lbs. of coffee, 50,000 tons of coal, 16,000,000 lbs. of cotton, and 280,000 lbs. of indigo. In the year 1846 the export of wine amounted to 30,000 pipes, nearly all of which went to the West Indies.

BARGE COURSE, a term applied to that part of the tiling of a roof which projects over the gable end of a building; the under part of which is stuccoed. To protect this stucco from the weather, two boards, called *barge-boards*, following the inclination of the roof, are often attached to the gables of old English houses, fixed near the extremity of the barge-course, and carved in the gothic style.

BARI, TERRA DI, a province in the kingdom of Naples, is rich in grain. Two kinds of it are cultivated, the common wheat for bread, and a small-grained hard wheat (grano duro) which is preferred for maccaroni, and is exported to Naples and elsewhere under the name of Barletta corn, from the harbour of Barletta where it is shipped. The principal farmers of this part of the province have formed themselves into a company, so that the corn trade of Barletta is entirely in their hands. The other crops are olives, tobacco, cotton, flax, almonds, and other fruits. Capers, liquorice, and the soda plant are also abundantly grown. The best wines are those of Trani, Bitonto, and Terlizzi. A little silk is produced. The fisheries and saltworks along the coast are very valuable. The province has no manufactures of importance; but shipbuilding is carried on in most of the towns along the coast. The trade is chiefly carried on by sea with Naples, Venice, Trieste, and the coast of Dalmatia, and consists of the agricultural products mentioned above.

BARILLA is the commercial name given to the impure carbonate of soda imported into this country, principally from Spain, the Canary Islands, and Sicily. The best is brought from Alicante, in the neighbourhood of which place it is prepared chiefly from the *Salsola soda.* The plants are usually gathered in September, and, after they have been allowed to become heated by being thrown together in heaps, are dried in the sun. In October

KNIGHTS CYCLOPÆDIA OF THE Industry of all Nations.

No. 9.

the plants are burned in a hemispherical kiln dug in the earth; the soda contained in them is fused and collected in masses, which have a hard and spongy consistence; and this soda, when broken into fragments, is ready for shipment.

The carbonate of soda is largely used in the manufacture of soap and glass, and for other purposes. From 1829 to 1834, the average annual importation of barilla into Great Britain was 252,000 cwts.; and at the present time it is hardly imported at all: in 1848 the import was only 2349 cwts. This change has been occasioned by the production of carbonate of soda from common salt through the agency of sulphuric acid: salt having become much cheaper from the repeal of the duty, and sulphuric acid also, from improvements in the manufacture. The quantity of carbonate of soda now consumed annually is calculated to be seven times as much as the largest importation of barilla in any single year. Barilla at present sells at 9*l.* to 10*l.* per cwt.

BA'RIUM, a peculiar metal, discovered by Davy in 1807: it is the basis of the alkaline oxide or earth *barytes*, from which it is obtained by various chemical processes. It resembles silver in appearance: it is much heavier than water. By exposure to the air it is slightly covered with a crust of barytes. It fuses before it becomes red hot, and at this temperature it acts upon glass, without being volatilized; when exposed to the air, and moderately heated, it burns with a deep red light. It may be flattened a little, so that it is to a certain extent a malleable metal. Barium has, however, as yet been obtained only in small quantities, and consequently its properties are but imperfectly known.

The protoxide is met with combined with sulphuric acid, forming *heavy spar*, or *cawk*, termed chemically sulphate of barytes, and with carbonic acid, constituting the mineral termed *witherite*, or carbonate of barytes; it may be procured by decomposing either of these native compounds. It is of a grayish white colour; when moistened with water it becomes very hot, und in a short time falls into a fine white powder; if more water is added, it becomes a crystalline and very hard mass. It is extremely poisonous, has an acrid, alkaline, caustic taste, and requires a high temperature to fuse it.

Barium combines with many substances to produce chemical compounds. One of the best known is *sulphate of barytes*, which occurs largely in many parts of the earth, especially in the lead mines of the north of England; it occurs both amorphous and crystallized. In the former state it is sometimes colourless and transparent, and frequently opaque. The crystals are often very large. It is extremely heavy, its specific gravity being about 4.7. It is unalterable by air or by water, and is scarcely affected by heat. When sulphate of barytes is only moderately heated with carbonaceous matter, a solar phosphorus is formed, which is called the *Bolognian Phosphorus*.

BARK. Several kinds of bark, being used for processes in the arts or for medicine, enter largely into commerce. Of the former class are oak bark, cork bark, mimosa or wattle bark, and quercitron bark; and the most important among the latter is Jesuits' or Peruvian bark. [CINCHONA.] Some others, such as CINNAMON and CASSIA, are noticed elsewhere.

Oak bark is extensively, and was formerly almost exclusively, used in tanning, for which it is valuable on account of the large proportion which it contains of the peculiar astringent called *tannin*. Sir H. Davy has shown that 8½ lbs. of oak bark are equal in efficiency to 2¼ lbs. of galls, 3 lbs. of Sumach, 7½ lbs. of the bark of the Leicester willow, 11 lbs. of the bark of the Spanish chestnut, 18 lbs. of elm bark, or 21 lbs. of common willow bark. The quantity of tannin, however, varies both with the age of the trees, and with the season in which they are cut; being more abundant in the bark of young than of old trees, while if taken in the spring the bark has four and a half times the quantity, in a given weight, that it would have in the winter.

Cork bark, or *Cork*, is the outer bark of an evergreen oak (*Quercus suber*), which grows abundantly in Portugal, Spain, the south of France, and Italy. Most of the cork bark used in Europe is supplied by Spain and Portugal, but that of the best quality by France. As the cork is really dead bark, it may be carefully removed without injuring the tree, which may be stripped every eight or ten years, beginning when it is fifteen years old. At each successive stripping the produce becomes greater in quantity, and better in quality. The inner bark, which contains much tannin, cannot be removed without destroying the tree. Cork bark is usually charred lightly when taken from the tree, to improve the texture by closing the pores; but this process, which is liable to impart a disagreeable flavour to liquors stopped with cork so treated, is not required for the thinner but closer layers of young bark. The lightness of cork recommends its use as floats for fishing-nets, for life-preservers, for insuring the buoyancy of life-boats, and for similar purposes; while its compressibility and elasticity, being combined with a closeness of pore which prevents the passage of liquids, render it valuable for stopping bottles and casks. [CORK-MANUFACTURE.]

Mimosa, or *wattle bark*, is collected from two species of Mimosa which abound in New South Wales, Van Diemen's Land, and New Zealand, where it is employed in tanning. It contains about 150 lbs. of pure tannin in a ton of bark, which is about three fifths of the proportion yielded by the best white oak bark; and it imparts a reddish colour to the leather.

Quercitron bark is the produce of the *Quercus nigra*, or *tinctoria*, a North American oak, and is used as a yellow dye. The colouring matter resides wholly in the inner bark; and care is needful in extracting it to avoid any admixture of the tannin of the bark, which would give a brown tinge.

The imports of bark for tanning in 1849 amounted to the very large quantity of 365,755 cwt., of which more than two-thirds were supplied by Holland and Belgium. Oak bark sells at present from 90*s.* to 130*s.* per ton.

BARK-BED, in Horticulture, is a bed formed of the spent bark used by tanners, placed in the inside of a brick pit in a glazed house, constructed for forcing, or for the growth of tender plants.

BARKER, ROBERT, deserves notice in this place as the inventor and patentee of panoramas. He practised originally as a portrait-painter in Dublin and in Edinburgh. The first picture of the kind which he painted was a view of Edinburgh, exhibited in Edinburgh in 1788, and in London in 1789, but with indifferent success. His second panorama was a view of London from the Albion Mills, and it was exhibited, with complete success, in Castle-street, Leicester-square, and afterwards in Germany. He built, and opened in 1793, with a panorama of Spithead, the present panorama exhibition-rooms in Leicester-square. He died in London, in 1806.

The chief characteristics of Dioramas and Panoramas are briefly noticed in later articles. [DIORAMA; PANORAMA.]

BARLEY is a grain too generally known to require a minute description. It is readily distinguished from other grain by its pointed extremities, and by the rough appearance of its outer skin, which is the corolla of the flower closely enveloping the seed, and. in most varieties, adhering strongly to it.

Of all the cultivated grains, barley is perhaps that which comes to perfection in the greatest variety of climates, and is consequently found over the greatest extent of the habitable world. It bears the heat and drought of tropical regions, and ripens in the short summers of those which verge on the frigid zone. In genial climates, such as Egypt, Barbary, and the south of Spain, two crops of barley may be reaped in the same year, one in spring from seed sown the preceding autumn, and one in autumn from a spring sowing.

Winter barley is mostly sown in those countries where the winters are mild, and the springs dry, as in the south of France, Italy, and Spain; or in those where the snow lies deep all the winter, and where the sun is powerful immediately after the melting of the snow in spring, as is the case in parts of Russia, Poland, and some parts of North America. In most climates, where the winter consists of alternate frost and thaws, and the early part of the spring is usually wet, as is the case in England, Scotland, and Ireland, the young barley is too apt to suffer from these vicissitudes, and the spring-sown barley gives the more certain prospect of a good crop.

The barley most commonly cultivated in England is that which has only two rows. It is almost universally sown in spring. The cultivation of all the varieties is nearly the same, and is best understood in the counties of Essex, Norfolk, and Suffolk, in which a great quantity of excellent barley is produced and malted for the London market.

The quantity of barley sown formerly was four or five bushels per acre: but, if the land is duly prepared and the seed good, from two to three bushels is an ample allowance. The best practical rule is, to sow as soon after the middle of March as the ground is dry. The practice of sowing clover, rye grass, or other seeds, with the barley, is almost universal, and is considered as one of the great modern improvements in agriculture.

The principal use of barley in this country, and wherever the climate does not permit the vine to thrive, and no wine is made, is to convert it into malt for brewing and distilling. The best and heaviest grain is chosen for this purpose, and, as it must have its germinating power unimpaired, the least discoloration, from rain or heating in the stack, renders it suspected, and consequently not so saleable. It is, however, still fit for being ground into meal, for feeding cattle and pigs, when it is not used for human food; or it may be made into pot barley by the process of shelling.

The produce of barley on land well prepared is from 30 to 50 bushels, and more, per statute acre, weighing from 45 to 55 lbs. per bushel, according to the quality. It is said to contain 65 per cent. of nutritive matter; wheat contains 78 per cent. A bushel of barley weighing 50 lbs. will therefore contain about 32 lbs. of nutriment; while a bushel of wheat weighing 60 lbs. contains 47 lbs. Good oats weighing 40 lbs. contain about 24 lbs. of nutritive substance; so that the comparative value of wheat, barley, and oats, in feeding cattle, may be represented by 47, 32, and 24, the measure being the same.

1,389,858 quarters of barley were imported in 1849; average price 27*s.* 9*d.*

BARLEY, PEARL, is the small round kernel which remains after the skin and a considerable portion of the barley have been ground off. Barley from which only the outer husk or skin has been removed is called *Pot Barley.*

Both these preparations of barley are made by means of mills constructed for the purpose, and differ only in the degree of grinding which the grain undergoes. In the mill originally used, and still common in Germany and France, the barley is rubbed between a pair of small mill-stones, the upper one of which has several grooves in its lower surface, mounted at such a distance from one another, that they rub without breaking the grains. This is *pot-barley;* and *pearl-barley* is produced by continuing the process until a further portion of the outside of the grain is rubbed off. The powder or meal which flies off through the perforated case forms excellent food for cattle, pigs, and poultry.

In another kind of mill, originally introduced from Holland, and generally used in Scotland, an ordinary grindstone of about three feet in diameter is made to revolve upon an horizontal axis, while a perforated case, similar to that above described, surrounds it, and revolves in the same direction, but with a much slower motion. The barley is admitted at an opening in the circumference of the case, and the effect is produced by the violent tossing which it receives between the stone and the case. This kind of mill is much more easily constructed and kept in order than the former, and is well adapted for use with hand-labour.

Pot and pearl-barley are very wholesome and nutritious, and it is to be regretted that they are not more used as food by the labouring classes of England, as they are in Scotland, Germany, and Holland. The essential oil of barley, which gives it its peculiar taste, resides chiefly in the skin and adjacent parts of the grain; the interior is a purer farina, more nearly resembling that of wheat. This farina, obtained by grinding pearl-barley in a common mill, is called *patent barley* and is used extensively for making barley-water; but if the essential oil possesses any medicinal properties, it is evident from what was observed before, that common pot-barley would be preferable for making a decoction of barley when prescribed as a remedy. The great use of pot and pearl-barley is in broths, stews, and puddings, as a substitute for rice. It swells, and unites well with the fat and oily matter extracted from meat in boiling. Even the bran, having been steeped in water, and allowed to ferment till it becomes acid, is relished by the humbler orders in the mess called *sowens.* In Holland, pot-barley, boiled in butter-milk and sweetened with treacle, is a common mess for children and servants.

BARM. [YEAST.]

BARMEN, a town in Rhenish Prussia, is a busy centre of industry. It is literally studded with cloth factories, cotton and silk mills, bleaching-establishments, dye-houses, soaperies, tobacco-factories, potteries, warehouses, and a variety of other buildings for the manufacture of linen, ironmongery, metal and plated goods, chemical products, &c. The annual value of the industrial products of this busy district are stated to be nearly a million sterling.

BARN, a building in which agricultural produce is stored, to protect it from the weather and keep it in safety. The thrashing-floor, which is required even where thrashing-machines are used for thrashing out the smaller seeds, is usually in the middle of the barn, and made of stone, brick, oak, or tempered earth; those of oak, formed of planks two inches and a half thick, dowelled or ploughed and tongued together, being considered the best; and it is often so arranged that a loaded waggon may be drawn in upon it, so as to throw the corn at once into the *bays*, or ends of the barn. Free circulation of air is important in all parts of a barn.

Barns are built of stone, brick, timber, or, in some places, of dry rammed earth in the manner termed *pisé.* If roofed with tiles, they should be bedded in coarse hay, which is more effectual than mortar in preventing the drifting of snow; and, if with thatch, reeds are to be preferred to any other material, because they afford no lodgment for vermin, and afford an excellent protection against the weather.

Hay is now seldom put in a close barn, experience having shown that it keeps much better in the open air in ricks. But where a considerable quantity of hay is tied up in trusses for the market, it is extremely useful to have a building with a roof to protect them from the wet, and to load the carts under shelter. For this purpose a kind of barn is contrived, which some call a *Dutch barn*, but which may very properly be called a *skeleton barn*, being the frame of a barn without the boarding. Another contrivance of similar character is used in Holland, in which a pentagonal thatched roof is made to slide up and down a series of vertical poles, on which it may be secured by pins at any required elevation. The lower ends of the poles are well braced together by a timber framing, which rests upon a brick foundation. Its chief use is for hay, which may be deposited safely in either large or small quantities, the roof being raised when additions are made, and lowered as the hay is taken off the top for use.

BARNARD CASTLE. This is among the busiest towns in Durham. The inhabitants are chiefly employed in the manufacture of carpets and shoemakers' thread. There are four large carpet manufactories and two thread mills, which employ several hundred hands. Many persons are engaged in the tanning business, producing a leather formerly highly esteemed in the manufacture of white leather breeches.

BARNSLEY, owes all its importance to its manufactures. Wire-works were in existence here in the time of James I., and the town had for a long period the reputation of producing the best wire in the kingdom. This manufacture has, however, greatly declined; and but little wire is now made in the town. Barnsley has lost its ancient trade, and has acquired a new one, to which its present prosperity is entirely owing; viz., the linen trade. Its fabrics are linen cloth, damasks, diapers, drills, ducks, checks, and ticks. The great improvements which Barnsley has made during a very recent period in the production of these articles, is a main cause of the prosperous state of the town. In damasks and drills it is said that Barnsley stands unrivalled. Some of the above goods are technically called *unions*, from both linen and cotton being united in their production. Much of the flax which is spun in the large flax-mills of Leeds is sent to Barnsley to be woven: there are, however, two flax-spinning mills in Barnsley. Weavers in this town are not generally employed in factories, but the manufacturers give out the yarn to them, which they weave at their own houses.

There are extensive bleaching works and dye-houses connected with the staple commodity of the town. The numerous coal-mines, and the iron-works in the immediate neighbourhood find occupation for hundreds of people; there are also several iron-foundries and a glass-house. The coal-mines became a subject of painful interest in 1847, when by an explosion at the Oaks Colliery 72 lives were lost.

All the varieties of Barnsley linen and flax manufactures will be illustrated by specimens at the Hyde Park Exhibition in 1851.

BARNSTAPLE, in Devonshire, enjoys the advantage of being the port for an extensive and improving inland district, and carries on a steady trade. There are lace-manufactories in the town, and also establishments for the manufacture of baizes, shalloons, tammies, hose, pottery, and fishing-nets, which afford employment to a considerable number of persons.

BAROACH, a city on the Bombay side of India, maintains a considerable trade with Bombay and Surat, to which places it sends cotton, grain, and seeds. This traffic is carried on in boats which draw little water, and which are impelled by large lateen sails.

BARO'METER, is the name applied to those instruments in which a column of air is weighed against a column of mercury.

Galileo, Torricelli, and Pascal, in the 17th century, successively made those experiments and observations on the pressure of the air, which led to the invention of the barometer. It was first found that the pressure of a column of the entire atmosphere is equal to that of a column of water (of the same diameter) about 33 feet high; it was next found that the pressure is equal to that of a column of mercury about 30 inches high; and it was afterwards ascertained that on a mountain the pressure will sustain a less height of mercury than at the earth's surface. These facts proved the existence of atmospheric pressure, and also the law of diminution in this pressure at different altitudes.

If a tube, closed at one end, be deprived of air, and the open end be immersed in mercury, the mercury will rise in the tube to the height of 28 or 30 inches, by the pressure of the atmosphere on the mercury in the vessel. Descartes, Huyghens and Dr. Hooke, devised barometers in which the use of one or more fluids of different specific gravity in connection with mercury was tried as a means of obtaining more distinct indications of very small changes of level; and many other forms of simple mercurial barometers have been constructed. One contrived by Amontons, consisting of a conical tube of glass closed at the smaller end, partially filled with mercury, and then inverted, is more simple and elegant in principle than any other; but the obtaining of a tube of the requisite accuracy is almost an ideal supposition. One contrived by Gay-Lussac for portable purposes permits the access of air to the mercury only by a hole too minute to allow the escape of mercury. Fortin's is a Torricellian barometer with a contrivance for raising or lowering the bottom of the cistern by a screw, so as to adjust the lower level of the mercury exactly to the zero point before commencing an observation. Hooke's *wheel barometer*, though too inaccurate for scientific use, is very much used as a weather-glass; for which it may answer well enough, if it be remembered that it is not the *state* of the barometer which furnishes any probable test of the weather, but the *change* which is taking place for the time being. This change is indicated by it pretty distinctly, though it cannot be trusted for showing either the exact amount of the change, or the exact height of the column of mercury. In this contrivance, a weight is placed on the mercury of a siphon barometer, and nearly counterpoised by another weight connected with it by a string, which passes over a pulley. The movement of the mercury causes this floating weight to rise and fall, and consequently the pulley, which carries an index, to turn more or less on its axis. The form of barometer invented by Gay-Lussac has been recently much employed in determining the heights of the mountains along the Anglo-American frontier in New Brunswick.

To observe the temperature of the mercury, which, by altering its bulk, affects the indications of the barometer, a thermometer is attached to the best instruments, the bulb of which is in the cistern.

In using the barometer as a weather-glass, it must be remembered that no rule which can be given will always hold true. The rising of the mercury usually presages fair weather, and its falling foul weather, as rain, snow, high winds, and storms, the lowest fall being found in great winds, though unaccompanied by rain. In very hot weather the falling of the mercury usually foreshows thunder; in winter, the rising presages frost; in frosty weather a continued fall foretells a thaw, and, in a continued frost, a rise indicates the approach of snow. If a change of weather follows very close upon a change in the barometer, it may be expected to last but for a short time, and *vice versâ;* and where the motion of the mercury is unsettled, changeable weather may be anticipated.

The mountain barometer, used for determining the altitude of mountains, is the most scientific form which the instrument assumes. All the resources of the instrument maker are here brought into requisition; and many of our distinguished philosophers have devised forms of the instrument known by their names. Among the more recent changes in this instrument are two for which Mr. Bursill obtained patents in 1841, intended to obviate certain slight inaccuracies in the ordinary forms. Another kind of mountain barometer was patented by Mr. Readman, in 1842. Mr. David Napier, in 1848, patented a barometer of such ingenious construction, that it can not only mark the entire course of atmospheric pressure for a continuous period of 24 hours, but can register its own observations on a piece of paper.

Sir John Robinson has contrived a simple substitute for the complex mountain barometer. It consists of a wooden box, containing a thermometer and a number of tubes, of a bore somewhat wider than those of self-registering thermometers, open at one end, and blown into bulbs at the other; there is also a small vessel of mercury. The observer notes the thermometer at each station on the mountain and immerses the end of one of the tubes in the mercury. When the observer descends to a lower level, mercury will be found to have entered each tube, to a greater height according to the height of the station to which each tube refers. By exposing each tube to an air-pump, exhausted till the mercury stands at the same height as at the station, the atmospheric pressure at that station becomes determined.

The making of barometer and thermometer tubes is among the curiosities of the glass-manufacture. Few manipulative processes are more striking. The workman collects a quantity of melted glass on the end of a tube, rolls it into a cylindrical form, blows through the tube to hollow the glass within, and holds it up to enable another man to attach a rod to the other end of the glass; the two men then walk backwards in opposite directions, to a distance of forty or fifty feet, elongating the glass as they go, or rather allowing it to elongate itself; until that which was a short thick cylinder, becomes a long thin tube, with an equable bore throughout its whole length. The tube so made sinks gently to the floor of the glass-house; and when cold it is cut or broken into convenient lengths.

The filling of the tubes with mercury, and the adjustment of the scales, are delicate processes in the manufacture of a good barometer.

A remarkable modern form of this instrument has been already described. [Aneroid Barometer.]

BARREL. In the old English measures a barrel was used to denote

31½ gallons of wine,

32 gallons of ale,
36 gallons of beer.

But these measures were altered in the reign of William and Mary, and of Anne; and when the imperial measures were introduced (1835) the contents of a barrel were thus determined:—

	Imp. Galls.
Wine barrel	26¼
Ale ditto (London)	32$\frac{32}{55}$
Ale and beer ditto (England)	34$\frac{34}{55}$
Beer ditto (London)	36$\frac{32}{55}$

Many other barrels have been in use to denote certain quantities of goods usually sold in barrels; thus the barrel of salmon or eels = 42 gallons, that of soap 256 lbs., &c.

The word barrel means, in common use, also any hollow cylinder, such as the barrel of a gun, a jack, or a hand organ.

BARREN LAND, in Agriculture, is that in which the plants generally cultivated do not prosper or arrive at maturity. This barrenness may arise from various causes. The texture of the soil may be such that the moisture essential to vegetation cannot be retained; or that the fibres of the roots cannot penetrate in search of food. In either case it is seldom that the soil can be rendered productive, so as to repay the expense of cultivation. There are, however, in all countries tracts of land which are barren and waste in their present state, but which, for want of better soils to employ and feed an increasing population, are well worth improving, and will ultimately repay the labour bestowed on them. The relative acreage of cultivated and uncultivated land in the British Islands is estimated as follows:—

	Cultivated. Acres.	Uncultivated. Acres.	Total. Acres.
England	26,632,000	6,710,400	33,342,400
Wales	3,117,000	1,635,000	4,752,000
Scotland	5,265,000	14,473,930	19,738,930
Ireland	12,125,280	7,316,664	19,441,944
British Islands	383,690	735,469	1,119,159
Total	4 522,970	30,871,463	78,394,433

Looking at this table, it is impossible not to ask whether so very large a proportion of the surface of the British dominions in Europe may not remain uncultivated, more from want of industry and skill than from insuperable barrenness?

The most prevalent causes of barrenness in land are a deficiency or an excess of water: the methods of remedying these are explained under IRRIGATION and DRAINING. Supposing that the moisture has been regulated, and that the land is to be brought into cultivation, the first thing to be done is to remove obstructions and impediments, whether they be rocks, stones, trees, or shrubs, or only the heath and coarse grasses which generally cover waste lands. When the surface is very uneven, so as to form hillocks and hollows, in which the water is apt to stagnate, levelling is a necessary process. The most effectual way of doing this is by the wheelbarrow and shovel; but, if the soil is loose and sandy, it may be best done by means of the *mollebart*, a Flemish instrument, consisting of a kind of large shovel, drawn along by a horse, and guided by a man. The small fields of Flanders are often levelled by this means. In France a somewhat more complex kind of mollebart has been patented.

The land being thus so far prepared the skill of the agriculturist is made available to determine on the crop, and to suit the soil for that crop. Some soils in this condition, require only exposure to the air; others require manure; others marling and ploughing; others a course of turnip husbandry; others a season of pasturing; &c.

The unproductive state of waste lands in many populous countries has suggested the employment of the poor and friendless on their improvement; and it has been thought a more enlightened charity to expend the money, which would otherwise be given in simple temporary relief, in such a manner as to make the labour of paupers available to their future comfort and independence. It is near increasing manufactures, where land acquires a greater value, that barren land is soon converted into fertile fields. It is there also that the improvement of waste lands is most profitable. The neighbourhoods of Aberdeen, Birmingham, Manchester, and Sheffield, among many others, furnish examples of the greatest industry and perseverance in overcoming the natural barrenness of the soil.

BAR-IRON. This important material of manufactures is noticed under IRON-MANUFACTURE.

BARTER is the exchange of one thing for another. The term is properly applied only to the exchange of movable things. Barter is simply the giving of one movable thing for another, without reference to any standard of value.

If two persons exchange things with reference to a money value, as if one man gives one hundred pounds' worth of wheat at the current price for one hundred pounds' worth of cotton wool at the current price, the transaction is still exchange or barter: the price has only been used as a means of making the exchange a fair transaction. If two persons exchange things on which they have agreed to put a money value, and the two things have an unequal money value, so that one party has also to give a sum of money to another, the transaction may be considered a *sale*.

Pure barter only takes place among barbarous nations, or between barbarous people and the traders of civilized nations. The exchanges of civilized nations are effected in the form of sale, which is more convenient for all parties.

BARYTES. [BARIUM.]

BASALT, a hard dark-coloured rock of igneous origin. It can only be considered as a variety (and a comparatively recent variety) of that mass of melted rock which has been ejected at various periods from beneath the crust of the globe, and to which various names have been assigned, according to the characters which circumstances have impressed upon different portions of it. Basalt is a rock of very extensive occurrence on the surface of the earth, and is very frequently found in the vicinity of volcanoes, both extinct and active. The greatest mass yet observed is that noticed by Colonel Sykes in the Deccan, constituting the surface of many thousand square miles of that part of India. When basalt occurs in horizontal tabular masses, and is columnar, the columns are generally perpendicular. When basalt forms the substance of a perpendicular dyke, cutting through other rocks, and is columnar, the columns are usually horizontal. Basaltic columns are sometimes also curved, and of this mode of occurrence there is a beautiful example in the island of Staffa.

When basaltic columns are jointed, and exposed to the destructive action of breakers on a coast, they often present the appearance of some great ruined work of art. Such deceptive appearances are, however, not confined to coasts, for in some countries, and especially in India, masses of basalt rise suddenly from the plains, and the broken columns, shooting upwards, may readily at a distance be mistaken for buildings. When viewed from above, the heads of a number of basaltic columns, if unbroken, appear like a pavement composed of numerous polygonal pieces of stone fitted into each other.

BASCINET, BASINET, or BASNET, was a light helmet, so called from its resemblance to a basin, generally without a visor, though it appears that the visor occasionally accompanied it.

BASE, or BASS, a name sometimes given to the VIOLONCELLO.

BASEL, BASLE, or BALE. The chief manufacture of this important town and canton is silk ribands; which are exported to the amount of 12,000,000 francs annually, principally to America. The transit trade also employs many hands. Business in Bills of exchange, and the wine and book trade are also considerable. There are likewise large tanneries, tobacco manufactories, &c. Basel stands at the termination of three great lines of railway.

BASEMENT, in Architecture, is the lowest story of a building, forming the base of a private house or public edifice. In edifices used as dwellings the basement is high; but in churches and other public buildings it is usually kept low. In basements the masonry is usually rusticated and set upon a plinth, on which there is sometimes a moulded base; the upper part of the basement is surrounded with a broad band, under which, at times, mouldings are employed. A cornice is also used occasionally instead of the band.

BASI'LICA. The Romans gave the name of Basilicæ to those public buildings with spacious halls, often surrounded with wide porticoes, many of which were built at different times in the various Fora of Rome. They were usually called after the person who caused them to be built.

The principal feature of the Basilica was a large roofed building, supported on columns. The roof, which was called the *testudo*, rose high above the other part of the structure, which consisted of two galleries, called *porticus* placed one above the other, and round the internal sides of the central building. The porticus was covered with a lean-to roof, the upper part of which commenced below the capitals of the columns which supported the testudo. The light was admitted between the spaces formed by the under line of the architrave of the testudo, the upper line of the lean-to roof, and the perpendicular lines of the columns. At the end of the central part of the interior a raised platform formed the tribunal for a magistrate.

It is probable that Rome possessed Basilicæ in all the different Fora of the city. Of these the Basilica Ulpia, which formed a part of the Forum Trajanum is the only one of which there are considerable remains left. Another Basilica, of the Corinthian order, was discovered on the Palatine Hill. A large edifice in the Forum, called the Temple of Peace, has also been named the Basilica of Constantine.

The most perfect Basilica of antiquity exists in Pompeii, constructed on the south-west, and consequently the warm side of the Forum. This edifice is 220 feet by 80. The testudo rose to the height of about 60 feet, judging from the diameter of the portions of the columns still remaining.

The early Christian churches of Rome may be considered as the best resemblances of the Roman Basilicæ. Not only the apsis, but the general form of the nave and aisles, of our ancient cathedrals is evidently borrowed from the Italian church Basilica.

BASIN is a geographical term which is used in such expressions as the basin of a sea, the basin of a lake, the basin of a river; and it includes all the countries drained by the waters that run into such sea, lake, or river.

If the basin of a sea runs far inland, and comprehends a great extent of country, it commonly contains large and fertile plains, maintains a numerous population, and at some period of history civilization has made considerable progress within its limits. Thus the basin of the Bay of Bengal comprehends countries not much less than half of Europe in extent. Accordingly we find, not only that it is, and ever has been, much frequented by vessels, but also that at a very early period civilization made considerable progress, and that at all times the arts of peace have been greatly cultivated within the limits of this basin.

On the other hand, if the basin of a sea is of small extent, the surrounding country is poor, its inhabitants backward in civilization, and its ports only occasionally resorted to by vessels. Such is the case with the Arabian Gulf, of which the basin commonly coincides with its shores, and in no place probably extends more than twenty miles inland.

The basins of lakes offer likewise several varieties. Those which are commonly called mountain-lakes, but with more propriety valley-lakes, have in general a very narrow basin, being inclosed on all sides by mountains. Many of them receive a river at one extremity, in which case their basin runs up such river to its source. The lakes of plains have in general a much larger basin, as they receive the drainage of a more extensive country, as the lakes of North America, and those of Russia.

In its geological sense, a basin indicates a depression or concavity of strata. Thus, the tertiary basins of London, Hampshire, and Paris, resting on chalk; the coal-basin of South Wales, resting on old red sandstone; and, in a larger sense, the European basins between the Ural, the Scandinavian chains, and the Pyrenees, Alps, &c. Some of these basins are due to the original circumstances of deposition, others have acquired their configuration from elevations and depressions of particular geographical areas.

BASKET-MAKING. Baskets have been made from the earliest ages, in most countries where pliant willows, reeds, or grasses are to be met with. In England the osier or willow is chiefly used for this purpose; and many of the specimens produced are exceedingly elegant. The willow twigs or other materials are prepared in various ways, according to the costliness of the basket to be made; and the manufacture consists in a kind of interlacing, very simple in its character, and requiring the aid of but few tools. Any of our excellent Blind Asylums, where industrial pursuits are carried on, will afford a pleasing exemplification of the ease with which basket-making can be carried on by blind persons.

A very large per-centage of the baskets bought by the middle and working classes in London, are made by poor persons, whose wives and children hawk them about the streets for sale. It is precisely one of those trades likely to put on such a commercial aspect—easy to learn, and requiring little or no capital to carry it on.

Foreign baskets are imported to a considerable amount—about 30,000*l.* in the year 1849.

BASQUE PROVINCES. The inhabitants of these Spanish provinces are very industrious. Most of them are engaged in agriculture, which is better understood than in most parts of Spain. Oxen are used in ploughing, but spade husbandry is the system chiefly adopted. The peasantry live generally in *caserios*, or hamlets of six or eight houses. Each farmer is the proprietor of the land he tills. The chief crops raised are wheat, barley, oats, maize, fruits, hemp, flax, and pulse. Some poor wine called *chacoli* is made; but the common beverage is cider, apples being very abundant. The chief iron mines and smelting furnaces of Spain are in these provinces. The ores are very rich; those of Somorrostro yield 33 per cent., those of Mondragon 40 per cent. of metal. Copper, tin, marble of different colours, and jasper, are also found. The preparation of charcoal, and the important fishery on their long extent of seaboard afford employment to those not engaged in tillage of the soil, or in the iron works. The number of corn-mills for grinding flour, which is one of the principal exports, is very great. Somorrostro, one of the towns, is celebrated for its iron-mines and iron-works, in which about 6000 tons of iron are annually made.

BASRA, BASSORA, or BUSSORA, the chief town of the Turkish district of Basra, is the chief inlet by which the products of Hindustan and the eastern countries are introduced into the Turkish empire. Its commerce is therefore considerable. Six or eight British ships arrive annually, but the chief part of the commerce is carried on in Arabian vessels, which belong to the merchants of Muscat. The imports consist of indigo, sugar, spices, &c., from Hindustan, tin from Banca, shawls from Persia, pearls from Bahrein, and cotton and woollen goods and cutlery from Europe; the exports, of bullion, copper, dates, raw silk, horses, and drugs. The export of dates has sometimes exceeded 10,000 tons in a year. The trade in the interior is chiefly carried on by caravans to Aleppo and Bagdad.

BASSA'NO, a town in the delegation of Vicenza, in Austrian Italy, is a place of great trade: it has manufactures of woollen cloths, straw hats, and tanneries; and it exports a great quantity of silk, the produce of its own territory.

BASSET-HORN, is a clarinet of enlarged dimensions, and the bell end is wider. On account of its length, the tube, which consists of five pieces, is bent inwards, forming a very obtuse angle. The scale of this instrument embraces nearly four octaves—from C, the second space in the base, to G in altissimo, including every semitone; but its real notes, in relation to its use in the orchestra, are from F below the base staff, to C, the second leger line above the treble.

BA'SSIA, is a genus of tropical plants, which yields many valuable substances. The *Bassia butyracea*, the Indian butter-tree, yields a fat-like substance, which is a kind of vegetable butter. The *Bassia longifolia*, the Indian oil-tree, has a yellowish fruit, from which is obtained by pressure a valuable oil, used by the poorer natives of India, for their lamps, for soap, and, instead of better oil, for cookery. The flowers also are roasted and eaten by the Indian peasants, or bruised and boiled to a jelly, and made into small balls, which are sold or exchanged for fish, rice, and various sorts of small grain. The wood is as hard and durable as teak, so that this is one of the most generally useful trees found on the continent of India. The *Bassia latifolia* has hard and strong wood, flowers which yield a spirit by distillation, and seeds from which a considerable quantity of greenish yellow oil is obtained, which is found useful for the supply of lamps. The *Shea tree*, another species, is the *butter tree*, so very important an article of African internal commerce.

BASSO DI CA'MERA, a double base, or *contrabasso*, reduced in size and power, but not in compass, and thus adapted to small or private rooms. It has four strings; two of gut, and two covered with silver wire, all unquestionably thicker than those of the violoncello, and tuned in 5ths, to the same literal notes as the violin, but two octaves lower than the latter.

BASSO-RILIEVO. The Italian term basso-rilievo, or the French bas-relief, is commonly applied to any work of sculpture connected more or less with a plane surface or background, and in this general sense is opposed to insulated detached figures, or sculpture in the round. In its more particular meaning basso-rilievo, low or flat relief, is usually appropriated to figures which have a very slight projection from the ground. *Alto-rilievo*, on the other hand, is not only rounded to the full bulk, but has generally some portions of the figures quite detached; and *mezzo-rilievo*, a style between the two, although sometimes rounded to a considerable bulk, has no part entirely unconnected with the plane surface or ground.

The British Museum contains unquestionably the finest existing specimens of this branch of sculpture in the rilievi which decorated the Parthenon, or Temple of Minerva, at Athens.

BASSOON, a musical instrument blown through a reed. It consists of four tubes of wood, bound together and pierced for ventages, of a brass craned neck, in which the reed is inserted, and of several keys. The whole length of the tubes is 6½ feet, but by doubling up this is reduced to four. It may be considered as a base oboe, and its compass is from B flat, below the base staff, to B flat, in the treble staff.

The *double-bassoon* is a bassoon of increased dimensions, the scale of which is an octave below that of the ordinary bassoon. The Serpent and the Ophicleide now supply the place which it was meant to fill.

BASTENNES, a village in the French department of Landes, is noted for a rich asphalte mine, which is said to yield more bitumen than the mines at Seyssel. The bitumen at Bastennes is very much used as cement for stone or wood; and when mixed with pebbles it forms an excellent pavement. Its adhesiveness is so great, that stones cemented with it cannot be separated by a less force than is sufficient to break them.

BASTI'A, the most populous and most commercial town in the island of Corsica, has manufactures of shoes, glove-leather, soap, wax candles, and liquors. The exports consist of wine, oil, hides, timber, and cattle. Fishing gives employment to a large part of the population. Steamers ply regularly every week between Bastia and Marseille.

BATAVIA, a city on the north coast of

Java, is an important place, from its excellent bay and its advantageous position for European commerce. It is the chief Dutch settlement in the east, and is a place of much trade. The Chinese carry on much traffic there. The town is unhealthy; but the country around is very beautiful and fertile, producing pine-apples, oranges, shaddocks, lemons, limes, mangoes, bananas, grapes, melons, pomegranates, custard-apples, papaws, mangosteens, and rombusteens, with many others mostly unknown in Europe. The chief imports are opium and piece goods; the exports, sugar, coffee, and spices: salt also forms an important article of colonial commerce. Near Batavia there are some very extensive works for making salt from sea-water.

BATHS AND WASHHOUSES. The practice of bathing is one which is too much neglected in this country. In the east, and at Rome in ancient times, the arrangements for bathing show much completeness. Some of the finest buildings at Rome were Baths. There were sixteen public baths at Rome in the time of Augustus, besides many sumptuous private baths; the public baths named after or by Agrippa, Nero, Titus, Domitian, Caracalla, and Diocletian, have acquired quite a European celebrity for their vastness and splendour.

In England domestic bathing is far too little practised. As metal-work becomes cheapened, the means of so doing are placed more and more within reach of the middle class. The *shower-bath*, especially, is becoming more and more efficient and economical. One form, recently introduced, is a kind of funnel turned upside down, with a colander or perforated plate placed over the open surface of the funnel; the small end is held in the hand; and as long as that exit is closed so as to prevent the admission of air, no water can flow from the colander; but as soon as the small end is opened, water flows through the perforations. The bather therefore keeps his finger on the small end of the machine until ready for the flow of water. Another bath has been more recently introduced, in which there are two holes stopped by the two thumbs at the lower part of the apparatus; it is more convenient than the other, inasmuch that the hand has not to be held so high above the head.

An ingenious improvement on the common shower-bath was made in 1844 by Messrs. Lewis, who registered their invention. It consists in making the water flow out at various heights and in various directions; and it is designated by its inventors by the somewhat learned name of *omni-directive*. Water is in the first instance poured into a reservoir at the bottom, whence a small hand-pump forces it to a reservoir at the top. From this upper reservoir it is made to descend in a great variety of ways. By pulling one particular string, the water descends perpendicularly, as in the common shower-bath. By pulling another string, it descends along five tubes which extend the whole height of the bath, round the outer circumference; and as these tubes have small orifices on the side next the bather, he can have a number of little streams pouring upon him from all directions. By moving one or more slides, he can close any number of these orifices in the tubes so as to limit the streams of water to particular directions. By turning a handle, and holding a small leathern pipe in the hand, the bather can discharge a more copious stream in any required direction; and by moving another handle at the bottom of the bath, he can obtain an upward stream. The apparatus is somewhat complex; but it certainly is 'omni-directive.'

The public baths in England are very few in number; and being also too high-charged to meet the wants of the operative classes, a happy suggestion was made to combine cheap public *baths* with public *laundries*. It was in 1844 that an association was formed in London, for 'Promoting cleanliness amongst the Poor;' and this association has been the forerunner of an amount of good which can hardly be calculated. At first it was a *charitable* undertaking, supported by the benevolent; then it was regarded as a *commercial* undertaking, planned so as to support itself; and at last it has assumed the form of a *corporate* undertaking, supported by parish or borough funds. All three varieties do, indeed, exist at the present time; but it is the last of the three which will probably be developed to the greatest extent. Public washhouses and laundries were formed in Glasshouse Yard, in Whitechapel, and in George Street, Hampstead Road; and these having been found very advantageous, an Act of Parliament was passed in 1846 empowering parishes and boroughs to construct baths and washhouses, under certain regulations. Few recent statutes have worked so much good, silently and unostentatiously. Baths and washhouses have been formed, and are now being formed, not only in various parts of the metropolis, but in most of the populous towns in England.

In the George Street Baths, in the six months from March to September, 1850, there were 63,000 persons who used the baths, and 36,000 who used the washhouses.

It is gratifying to learn that the French National Assembly has just voted 600,000 francs for the establishment of Baths and Washhouses.

BATTENS are pieces of timber 6 feet or more in length, 7 inches in width, and usually from 2 to 2¾ inches in thickness. *Deals* differ from battens in being always above 7 inches wide, and *batten-ends* in being under 6 feet long. These are merely technical distinctions used in the timber trade.

BATTERIES, ELECTRICAL AND GALVANIC. All that need be said on this head in the present work, will be found under ELECTRO-METALLURGY and GALVANISM.

BATTLE-AXE, a military weapon of offence used in different countries from the remotest times. The introduction of the battle-axe into this country has been attributed to the Danes: but proofs of an earlier use of it in our islands are deducible. That it was used in England in the Saxon times appears from several MSS. of the ninth century; and the English are represented as using it, in the Bayeux tapestry. The pole-axe, with an edge on one side and a sharp point on the other, is believed to have come in with the Normans. The use of the battle-axe declined during the middle period of English history.

BATTLEMENT, a parapet wall, commonly employed in castellated and in ecclesiastical edifices of that kind which are distinguished by the general name of Gothic. The battlement was originally designed for the protection of the besieged, but afterwards became merely an ornament to the edifice. The battlement is generally indented, with a coping inclined both ways from about the centre; the lower part between the coping and the cornice of the building is often pierced and decorated. Mr. Rickman has described the characteristic features of the Norman, Early English, Decorated English, and Perpendicular English styles of battlements.

Castellated battlements have the embrasures between the battlements sometimes nearly equal to the width of the battlements themselves; sometimes the embrasures are narrow, and the battlements wide, with the coping moulding placed horizontally and the sides cut plain. Another battlement consists of a moulding running round the battlement and the embrasure, while a capping is set upon the horizontal part of the embrasure and battlement, as at York Minster.

BAVARIA. This important country, like most others which have mountain ranges as well as wide plains and river valleys, is rich in varied produce. Few countries possess a more productive soil than Bavaria. Agricultural industry is principally directed to the cultivation of wheat, rye, barley, and oats. The grape is much cultivated in Bavaria, especially for the Franconian, the Steinwein, and the Leistenwein varieties. About 20,000,000 English gallons are supposed to be an average produce of Bavarian wines. Among other articles of Bavarian vegetable produce are hops, tobacco, flax, hemp, linseed, rapeseed, mulberry-trees for silk rearing, fruits of many kinds, coriander and other seeds, madder, the potato, and fodder for cattle. Most of the mountains are finely wooded.

The principal mineral products are iron, coal, and salt; gold and silver are found in small quantities, only in the waters of the Inn, Rhine, Danube, and Isar; quicksilver, in the circle of the Rhine; and copper, which was formerly raised in several quarters, is now confined to the works at Kahl and Kaulsdorf, in the circle of the Upper Main. There are two mines of cobalt also on the latter spot, from which small quantities of tin, lead, and antimony have occasionally been obtained. The Upper Main, Rhenish Bavaria, Regen, Lower Danube, and Isar territories are the chief mining districts in Bavaria. Among the other mineral produce may be named black lead, sulphur, porcelain earth, marble, alabaster, rock crystal, asbestos, and many of the gems.

In Bavaria, as in many other German states, the profits arising from vast establishments, and the concentration of productive powers, are comparatively unknown; manufacturing industry is mostly diffused over a multitude of adventures on a small scale. The manufacture of linens, which is the chief, is not confined to a few large establishments, but is scattered over the whole state, and in many districts the agricultural population partly maintain themselves by weaving linen. Linen-yarn is also spun in some districts, but not to any great extent, and chiefly for exportation. The manufacture of woollens and worsted hose is carried on principally in Ansbach, Baireuth, Lindau, Munich, and the Upper Palatinate; but this branch of industry is in the hands of individuals, and not carried on in large factories. The supply is very inadequate to the consumption of the country, and sometimes the excess of imports over exports has amounted to 40,000*l.* per annum. There is a similar deficiency in the domestic supply of manufactured cottons; the use of improved machinery, however, is gradually increasing in many quarters, and additions are constantly making to the number of spinning-mills. The districts about Augsburg, Kaufbeueren, and Hof are the most important seats of this branch of Bavarian industry, and numbers are also employed in hand-spinning. The leather manufactories are of considerable importance, but mostly carried on by numbers of small manufacturers. Bavarian calf-skins are in great repute and largely exported, but sole leathers are not produced in sufficient quantity for the home demand. The supply of paper, of which Aschaffenburg, Nürnberg, Fürth, Augsburg, and Schwabach furnish many fancy sorts, is beyond the domestic consumption. Schweinfurt and Mainberg possess large manufactories of paper-hangings, which are of excellent quality, and in much demand in other German states. Straw-platting has increased considerably of late years. The manufacture of looking-glasses and of glass for optical purposes is in a high state of efficiency in Bavaria; and the glass manufactures generally are very extensive. The manufacture of articles in wood, and the felling, hewing, and general manufacture of timber occupy thousands of hands. There are nearly 2000 sawing-mills in Bavaria for the preparation of boards, deals, and laths; and almost as many families are wholly supported in Ammergau and Berchtesgaden by the manufacture of articles in carved wood, some of which are very beautiful. There are several porcelain manufactories at work; that at Nymphenburg, not far from Munich, produces china which may bear comparison with the finest in Europe. The potteries and the slate-works are numerous. The working of the metals chiefly consists in extensive manufactories of ironware, especially nails and needles, the export of which is considerable. There is a manufactory of arms at Amberg which supplies the army. The gold and silver smiths of Munich, Würzburg, Nürnberg, and Augsburg, are in great repute. Fire-arms, fowling-pieces, cannon, brass-ware, gold and silver leaf, employ a large number of workmen. The brewing of beer, in many respects the most important branch of manufacture in Bavaria, employs upwards of 5000 establishments, or taxed brewers, by whom about one hundred million gallons of beer are annually made. Many establishments and institutions exist in Bavaria tending to the encouragement of manufactures.

Though Bavaria is an inland country, its trade is greatly favoured by its geographical position, which has rendered it in some degree a central point between the Mediterranean, the Baltic, and the German Ocean, and a medium of intercourse between the west and the east of Europe. Its excellent roads, rivers, and railways, have tended to the same result. The principal articles of export are grain, salt, timber, potashes, fruit, liquorice-root, seeds, hops, cattle, sheep, swine, fish, flax, yarn, coarse linens, glass, leather, beer, &c. The imports are principally wines, cotton, coffee, sugar, rice, tobacco, drugs, sea-fish, copper, oil, hides and skins, hemp and flax, silk and silk goods, woollens, lead, furs, honey, and cheese.

Bavaria being an inland country, all British goods reach there by indirect means; so that the amount can hardly be stated.

To the extent of her means, Bavaria is making preparations to occupy a place in the Industrial Exhibition of 1851. All the chief towns will be contributors, and many of the articles contributed will be of a peculiar character.

BAYEUX, a town in the French department of Calvados, is famous for its manufacture of lace. There is a manufactory for producing large lace-pieces, such as dresses, scarfs, shawls, mantillas, &c. These laces are exported to Spain, Mexico, the United States, and elsewhere. The porcelain of Bayeux maintains a very high repute. Muslins, serges, calicoes, table-linen, cotton yarn, leather, and hats are also manufactured.

BAYEUX TAPESTRY, a web or roll of linen cloth or canvass, preserved at Bayeux, upon which a continuous representation of the events connected with the invasion and conquest of England by the Normans is worked in coloured woollen thread, after the manner of a sampler. It is 20 inches wide, and 214 feet long; and is divided into 72 compartments, each of which bears an explanatory Latin inscription. It is stated traditionally to have been worked by or under the superintendence of Matilda, the Conqueror's queen, and presented by her to the cathedral of Bayeux, of which Odo, the Conqueror's half-brother, was bishop. It represents the minutest manners and customs of the earliest Norman lines in England, and was evidently designed while the particulars of the contest, of many of which it affords the only record known, were fresh in recollection. A curious illustration of its minute accuracy of detail occurs in the compartment representing the funeral of Edward the Confessor, where a person is represented placing a weathercock upon the spire of Westminster Abbey; indicating that the building was scarcely finished at the time of his decease.

BAYO'NNE, a town in France, on the confines of Spain, has extensive rope-walks, glass bottle factories, sugar refineries, ship building yards, and establishments for fitting out ships for the whale fishery. It is famous for its hams, for its liqueur-brandies, and for its chocolate. The trade of the town is very considerable. The exports consist of broad cloth, linen, silks, and other manufactured articles, wine, brandy, timber, planks, pitch and tar, drugs, &c. The imports are chiefly Spanish wool, saffron, liquorice, bullion, &c. The coasting trade employs the greater part of the vessels which enter or leave the port of Bayonne.

BAZAAR. In Turkey, Egypt, Persia, and India, this term distinguishes those parts of towns which are exclusively appropriated to trade. In this exclusive appropriation they resemble our markets; but in other respects they approximate more nearly to our retail shops.

The regular bazaars consist of a connected series of streets and lanes; and, when of a superior description, they are vaulted with high brick roofs. The domes or cupolas which surmount the vaulting admit of a subdued daylight. In the best specimens of the vaulted bazaar the passages are lined on each side with a uniform series of shops, the floor of which is a platform raised from two to three feet above the level of the ground, and faced with brick. As the vault springs from the front of the line of shops, they seem like a series of recesses, and the partition-walls between them appear like piers supporting the arch. These recesses are entirely open in front, in all their height and breadth; they are scarcely more than very small closets, seldom exceeding six feet in breadth, rarely so deep as wide, but generally from eight to ten feet in height, and occasionally more. But in the more respectable parts of large bazaars, there is generally a little door in the back wall which conducts to another small and dark closet, which serves the purpose of a store-room. The front cell is the shop, on the floor of which the master sits with his goods all around him.

The peculiar principle of the oriental bazaars is that all the shops of a city are there collected, instead of being dispersed in different streets as in Europe; and that in this collected form the different trades and occupations are severally associated in different parts of the bazaar, instead of being indiscriminately mingled as in our streets.

An English Bazaar, in which many different kinds of manufacture are assembled under the same roof, is not a good imitation of its eastern original.

BDE'LLIUM is a gum-resin, the produce of a species of amyris, or rather balsamodendron, a native of India. This substance occurs in masses sometimes as large as a walnut, in oblong or angular pieces of a yellow, red, or brownish colour. The clearest pieces are transparent; the odour is weak and peculiar; the taste bitter, balsamic, and resembling myrrh, or Venice turpentine. It is tolerably brittle at the ordinary temperature of the atmosphere, but with a slight increase of heat the finer kinds may be kneaded between the fingers.

Resembling myrrh in appearance, it also resembles it in its effects upon the human system, and is often fraudulently substituted for it: it is however weaker, while it is more disagreeable and acrid. It is now disused in Britain, but is found intermixed with gum Arabic.

BEACON, a sign ordinarily raised upon some foreland or high ground as a sea-mark. It is also the term used for the fire-signal which was formerly set up to alarm the country upon the approach of a foreign enemy. The power of erecting beacons as sea-marks was originally in the king, and was usually delegated to the lord high admiral. Many sea-marks, signal-posts, and substitutes for light-houses, are still called beacons.

BEADS. The manufacture of Glass Beads is carried on in the following manner, at Murano near Venice. Tubes of glass of various colours are drawn out to great length, in a gallery adjoining the glass house; in the same way as barometer and thermometer tubes are drawn out in an English glass house. The tubes are then cut into very small pieces of nearly uniform length, on the edge of a fixed chisel. These small pieces are put in a heap into a mixture of fine sand and wood ashes, and stirred about with an iron spatula till their cavities get filled. The mixture is transferred to an iron pan suspended over a moderate fire and continually stirred until the cylindrical bits assume a smooth rounded form. When removed from the fire, and cleared out in the bore, they constitute beads.

Foreign beads are imported to the value of 8,000*l.* to 10,000*l.* annually.

BEAN. There are two distinct kinds of beans cultivated; the one is our common garden or field bean: the other is the French bean, haricot, or kidney-bean.

The common bean, of which there are several varieties, bears a pod containing several oblong rounded seeds, which are used in the soft young state for the table, and in the hard dry state for domestic animals chiefly, either whole or ground into meal. The *Windsor* bean and the *horse* bean are the two chief varieties. The usual mode of sowing is to drill them by a machine, at the distance of from twenty to thirty inches, according to the richness of the soil; or to dibble them by hand. The soil best adapted for beans is a rich strong loam, such as produces good wheat. In such a soil the produce is sometimes fifty or sixty bushels per acre, but an average crop, on moderate land, is about half that quantity. The wheat which follows beans is generally good and heavy, and seldom runs to straw. In cold wet soils beans require great care to ensure good crops. Although the nutritious matter in a good crop of beans is great, and almost equal to that obtained from a crop of wheat, it exhausts the soil much less; and thus there is perhaps no crop bearing seed which gives so great a return with so small an expenditure of the nutritive juices of the soil.

The principal use of beans is to feed horses, for which purpose they are admirably adapted, and far more nourishing than oats. They should be bruised or split in a mill, and given to horses mixed with hay and straw cut into chaff. Great quantities of beans are consumed in fatting hogs, to which they are given whole at first, and afterwards ground into meal. Bacon hogs may be fatted almost entirely on beans and bean-meal. Bean-meal given to oxen soon makes them fat. All but the very best wheaten flour is adulterated with bean-meal.

The French bean, kidney bean, or haricot bean, is chiefly cultivated for its tender and succulent pod, being one of the most esteemed vegetables for the table. The dried seeds are also boiled after being soaked in water for some time, and are thus used very extensively by the French.

The imports of beans for three years were—

1846	..	255,047	Qrs.
1847	..	443,675	of
1848	..	490,353	beans.

BEAR. Many species of bear contribute in various ways to the arts and to domestic economy. In the Arctic countries the *brown bear* is hunted and taken in pitfalls and traps of various kinds; and in some countries, as Lapland and Kamtchatka, there is no part of the animal which is not turned to some useful purpose. The fur of the brown bear in youth is of a yellowish colour, excepting on the feet, where it is of a deep black. The *black bear* inhabits every wooded district of the American continent, from the Atlantic to the Pacific, and from Carolina to the shores of the Arctic Sea. Every where however its numbers have been greatly thinned, partly owing to the value of the animal's skin in commerce, and partly to the tide of European colonization. It must not, however, be imagined that 'bear's skin' gloves or other articles of dress are necessarily made from the skin of the animal whose name they assume. No part is useless to the American bear-hunter: the flesh, the fat, and the skin are peculiarly esteemed; and a feast of bear's flesh is conducted with many observances. Of the *Syrian bear*, the gall is in great esteem; the skins are sold, and so is the dung, which is used as medicine for diseases of the eye in Syria and Egypt. The fur is woolly beneath, with long straight or but slightly curled hair externally. Many other species of bear are occasionally captured for the sake of their furs. The bear-skins imported into this country in 1848 amounted in number to 9712, of which about two-thirds were from the Hudson's Bay Company's territories.

It is perhaps scarcely necessary to inform any reader of average intelligence, that the *bear's grease* so profusely advertised has, for the most part, had little indeed to do with the life or the death of bears. More is used every year in England than could be procured from the carcases of all the obtainable bears in all countries. Large quantities of the so-called bear's grease are made of hog's lard, palm oil, and flowers of benzoin.

BEARING, the direction of the line drawn from one point to another, is a term usually applied to the points of the compass. To take *bearings* is to ascertain the points of the compass on which objects lie. The distances of a ship from a headland may be found by observing its bearings at two different hours of the day, knowing the course or bearing of the ship's path and the distance sailed in the intermediate time.

BEAUCAIRE, a town in the department of Gard in France, is very advantageously situated for trade; whereby it has long been an entrepôt of the trade of France with Spain, Africa, Italy, and the Levant. One of the great old fairs of Europe is held here every year; when Greek, Armenian, Turkish, Egyptian, Arabian, Italian, Spanish, and Moorish merchants arrive to sell the merchandise of their respective countries and take away in return the manufactures of France. The concourse of people at this fair in ordinary times is said to exceed 100,000. For their accommodation a supplemental town, regularly laid out in streets, is built of tents in a vast meadow bordered with elm and plane trees, which extends between the Rhône and the ruins of the old castle. Here articles of every kind, whether of convenience or luxury, may be found; and in this city of canvas the main business of the fair is transacted. A tribunal consisting of twelve members settles any disputes between the buyers and sellers during the continuance of the fair. The prefect of Gard always attends and entertains the principal merchants and strangers. The transactions at this fair, which lasts two or three weeks, are said to cause an outlay of above 150 millions of francs, and to be so profitable to the good folks of Beaucaire, that when it terminates they resume the *far niente* habits of the south, having gained in one month wherewith to take their ease during the rest of the year.

The ordinary commerce of the town consists of corn, flour, provision stores, wine, oak planks, &c. The principal manufactures are hosiery, serge, silk stuffs, olive oil, pottery, and leather. The Arles and Lyon steamboats land and take up passengers at Beaucaire.

BEAUNE, an old Burgundian town in the department of Côte-d'-Or, in France, has manufactures of broad-cloth, serge, druggets, and great numbers of wine-casks. There are beet-root sugar-refineries, vinegar-works, dye-houses, breweries, and tanneries in the town, the trade of which consists in the products named, and in corn, cattle, and provisions. Beaune exports annually about 40,000 butts of wine.

BEAUVAIS, an ancient episcopal city of Picardy, has some very important manufactures. It has long been famous for its silk tapestries; broad cloths of every quality and colour, flannels, swansdowns, shawls, hosiery, cotton and woollen yarn, ribands, black lace, china, and chemical products, are also extensively manufactured. The greater part of the cloth worn by the French army is made at Beauvais. There are also several establishments for bleaching linen, besides tanneries, and dye houses. The commerce of the town consists of its industrial products and corn.

BEAVER. The beaver is almost as interesting to us as an *artificer*, in the formation of his retreat, as in respect to the valuable fur which he yields, and which has in past years been so largely used for hats (though less now than formerly). It is not only for its fur that the beaver is prized, but for a product called *castor*, found in certain glandular sacs, and used in medicine and perfumery. The fur of the beaver varies from glossy brown to almost black; the tail, or caudal paddle, used as a rudder in diving or ascending, is flat, scaled, and oarlike.

The beaver-skins imported in 1848 amounted in number to 41,132; almost entirely from the Hudson's Bay Company's Territories.

BEDFORD LEVEL. The Bedford Level is an instructive example of energy overcoming natural difficulties. The level comprises about 400,000 acres of flat country in the fen-district of Lincolnshire, Cambridgeshire, &c. There is abundant evidence that it was once a forest, and then a stagnant morass; and to bring the morass into the state of fertile corn-fields, has been the object of the Bedford Level Drainage. This drainage has been in progress, at intervals, for four centuries: the principal works being the construction of canals or artificial rivers to carry off the stagnant water to the sea. These rivers or 'cuts,' are several miles long, and of various widths.

One of the great works is that called the Nene Outfall, which includes a cut six miles long by 200 feet wide, and which was made at the cost of 200,000*l.*

At the present time very extensive operations are in progress. A fine bridge is being constructed over the Nene at Sutton Wash; the cuts and embankments in the northern part of the Level are undergoing improvements; and the whole of Whittlesea Mere is being drained. The public spirit and the private munificence which have marked the encouragement given to this useful enterprise by the successive Dukes of Bedford, well justify the name given to the Level.

BEDFORDSHIRE is the most purely agricultural county in England, having the smallest proportional number of inhabitants engaged in manufactures and trade. Indeed, it can hardly be said that the county contains any persons engaged in manufactures; the comparatively few persons so employed might with equal propriety have been included among the class engaged in trade or handicraft, their employment being for the most part that of straw-plaiting.

BEDSTEAD, the frame employed to support a bed. Bedsteads of iron and brass, of very light and simple construction, occupying little space, easily taken to pieces and put together, and affording the best security against the harbouring of vermin, have been much used of late years, and may be highly recommended as favourable to health and cleanliness. Mr. Winfield, the eminent brass manufacturer of Birmingham, patented many valuable improvements in metallic bedsteads, in 1848. In the next following year Messrs. Sturges and Harlow, also of Birmingham, patented other improvements in bedsteads, calculated to impart elasticity to various parts. The metallic bedsteads of Birmingham manufacture, and probably others from the continent, will occupy a place in the Industrial Exhibition of 1851.

Invalid bedsteads have been contrived, in which, besides offering facilities for performing surgical operations, dressing wounds, &c., ingenious mechanism has been applied to enable the patient to vary his position with very little labour or trouble; but all contrivances of this character fall short of Dr. Arnott's hydrostatic bed, or water-bed, in which a very soft feather-bed or mattress is laid upon a waterproof sheet floating upon the surface of a tank or vessel partly filled with water. The support offered by such a bed is so perfectly equable as to afford comfortable rest under circumstances where the unequal pressure of the body upon the softest ordinary bed would be painful and injurious; while its yielding character will in many cases allow the application of poultices, or the performance of other offices of the sick-chamber, without any alteration of the patient's position.

BEE. We can only notice this small but important insect, in so far as regards the *honey* and *wax* of the honey-bee. A colony of bees is termed a swarm, or a hive, and consists of three sorts, viz. males or drones, neuters or workers, and the queen or reigning female. A hive of bees, besides males, workers, and queen, consists also of eggs and larvæ, destined to form a future brood. The number of workers in a well-stocked hive varies from 15,000 to 20,000. The number of males, or drones is irregular; sometimes they amount to 1000, sometimes only to 600 or 700.

To the labours of the workers are due various products, as *honey*, *bee-bread*, *wax*, and *própolis*.

Honey.—Honey is the nectar of flowers, lapped out of the nectary by the tongue, and conveyed to the crop or honey-bag. Here it undergoes but little alteration (for honey extracted from some plants is poisonous), and is disgorged into the cells destined to receive it. Of these some are store-cells, others are filled for daily use. A single cell will contain the contents of many honey bags; and though the cell is horizontal the honey will not escape, for a thick cream arises, and forms a glutinous film obliquely placed, keeping in the treasure. The store cells, when filled, are covered with a waxed lid.

Bee-Bread.—While the bee is extracting the sweets of the flowers, it becomes covered with the pollen of the anthers; this pollen it wipes off from its body with the brushes of its legs, collects every particle together, and kneads it into two little masses, which are each placed in a sort of basket on the broad surface of the tibia or middle joint of the leg, where a fringe of elastic hair over-arches a concavity, and acts as a sort of lid or covering. Thus burdened, off the insect flies to the hive; first the honey is safely lodged, then the bee-bread, or kneaded pollen, is disposed of as circumstances may require. Sometimes it is eaten by several bees, called by a peculiar sort of hum to their repast, and if more is collected than required for present use it is deposited in some of the empty cells as a future provision.

Wax.—Wax is a peculiar secretion in little pouches or cells, beneath the scales of the abdomen. Of these pouches there are generally four on each side, at the base of each intermediate segment on the under surface, and concealed by the overlapping of the preceding segment. It would appear that by some internal process wax is elaborated from honey, as the wax-workers retain the honey when wax is required, which they would otherwise disgorge into the cells. The wax oozes out between the abdominal rings in the form of little laminæ; it is then worked with the mouth, and kneaded with saliva, that it may acquire the requisite degree of ductility for the construction of the comb.

Própolis.—This is a glutinous or gummy matter, employed for smearing or varnishing the waxen cells. It is procured from the buds of various trees, as the birch, &c. The bees procure this gum by means of their mouth, prepare it, load each hind leg with it, and so carry it to the hive. It is employed, not only in varnishing the cells, but in stopping up crevices, for coating the sticks which support the combs, and for mixing with wax, and patching up weak parts. Often it is spread interiorly over the dome of the hive, and it is mixed up with the wax forming the cells.

The marvellous instinct which impels the bee to construct its beautiful honey-comb, we do not touch upon here.

BEECH. The common beech, known in America as the *white* beech, is the most useful species of this valuable tree. The timber is hard, and is employed for a great variety of purposes. It is used for the keels and side planking of ships; for ringing mill-wheels; for making piles, weirs, sluices, flood-gates, and other constructions exposed to the action of water; for cogs of wooden wheels; for making bedsteads and chairs; for panels of carriages: for various articles in joinery, cabinet-making, and turnery; for numberless small articles of household furniture; for railway-sleepers; for barn-floors; for herring barrels; for wooden shovels and peels; for wooden screws and sieves. In Germany beech-wood is used for many of the purposes above-named; and also for gun-carriages, wheel-felloes, bowls, porringers, salt boxes, spindles, rollers, spinning-wheels, pestles, presses, bellows, and numerous other articles; while, sawn into thin boards, it is used for boxes, packing cases, sword scabbards, and even the boards of books (instead of millboard). In France, besides other purposes, beech is used for gun-stocks, plough socks, cricket bats, cheap knife-handles, and cheap *sabots* or wooden shoes.

Beech is used to an enormous extent in France and Germany for fuel. The bark is used in tanning. The dried leaves are said to form an excellent substitute for feathers in beds, and to be largely employed in such a way in some districts. The dried catkins of the leaves are used to stuff cushions. The *mast* or fruit is eaten by many animals; and from this fruit an oil useful for lamps and for cooking is obtained. A *Beech-Oil Company* was one of the most noted commercial speculations of Queen Anne's reign.

BEER-MACHINE. In the ordinary Beer Machine, each handle has a single action, that is, draws from one cask only; but in many respects it would be useful if two pumps could be worked at once by the same handle. From the rapid fluctuations which malt-liquor undergoes in quality, owing to changes in the weather, it is frequently necessary for the retailer to mix old and new beer together, in order to maintain a uniform quality. This is done either by drawing from two butts, by two pumps and two handles, or by mixing beer of two ages in the same butt, by which a liability to a new fermentation is incurred. To obviate these inconveniences was the purpose of Ernest's Beer Engines, patented a few years ago. The arrangement of this machine is very ingenious. One handle works the levers, rods, and pistons of two pumps, which may be connected with the beer in two butts. In the usual perpendicular position of the handle it works both pumps at once; but if drawn a little on one side, by a slight movement of the hand, it works one pump only; and it is optional with the drawer whether to work one or the other pump, or both, and whether to draw equally or unequally from both.

BEET. There are two distinct species of beet commonly cultivated, each containing several varieties, the one called *Beta cicla*, which produces succulent leaves only, the other *Beta vulgaris*, distinguished by its large fleshy root. The cicla is chiefly cultivated in gardens as a culinary vegetable, and forms one of the principal vegetables used by agricultural labourers and small occupiers of land in many parts of Germany, France, and Switzerland. The second species, the *Beta vulgaris*, or Beet-Root, has been long cultivated, especially that variety called the *red beet*, which, when boiled and sliced, makes such an excellent addition to salads.

The common field-beet for cattle, or *mangel wurzel*, which has been long known in Germany, was introduced into England at the latter end of the last century. There are few crops so valuable for winter food for cattle as the beet; Swedish turnips exceed them in the quantity of nourishment, weight for weight, but on good light soils the produce of the beet per acre is much greater. The *white beet* has been chiefly cultivated for the extraction of sugar from its juiee. It is smaller than the mangel-wurzel, and more compact, and appears in its texture to be more like the Swedish turnip. The beet-root sugar manufacture sprang up in France in consequence of Bonaparte's scheme for destroying the colonial prosperity of Great Britain by excluding British colonial produce. It having been found that from the juice of the beet-root a crystallizable sugar could be obtained, he encouraged the establishment of the manufacture by every advantage which monopoly and premiums could give it. According to Chaptal, the process is thus conducted. The roots, after being cleansed by washing and scraping, are rasped and reduced to a pulp in a rasping machine. When ground, the pulp is powerfully squeezed by a press, in canvass bags, to expel the juice, which is received in a copper. In this copper the beet-juice is heated to about 178° Fah.; lime-water is then added, and stirred up with it. Having been mixed with animal charcoal it is made to boil, by which both a scum and a sediment are separated from it. The clear liquor is drawn off, and is evaporated in shallow vessels; the process is continued till the juice becomes a thick syrup, which is then strained through a linen bag. The syrup is again boiled and skimmed and then transferred to a cooler, where it remains for a short time. It is next transferred to sugar moulds, and treated pretty much in the same way as the sugar-cane juice, described under SUGAR.

The beet-root sugar manufacture is said to be difficult to manage well; but the sugar when produced is equal to cane-sugar. Five tons of clean roots produce about 4½ cwt. of coarse sugar, which give about 160 lbs. of double-refined sugar, and 60 lbs. of inferior lump sugar. There is also a quantity of molasses, fitted to yield spirit, and the pressed refuse, which is good food for sheep and cattle. As a question of commercial enterprise, however, the manufacture of sugar frcm beet is not found profitable, wherever colonial cane-sugar is admitted at a reasonable rate of duty. There are beet-root sugar manufactories in Russia, France, Prussia, and many of the other German States.

BEIRUT, or BAIROUT, the Syrian port for Damascus, is the channel through which British goods find their way to Bagdad and Mesopotamia. There are about 400 laden vessels enter the port yearly. The imports consist of cambrics, cotton twist, calicoes, indigo, shawls, printed goods, shirtings, handkerchiefs, &c.: the exports are chiefly raw silk and cotton, skins, hides, madder, gum, galls, fruit, tobacco, sponges, &c.

BELFAST is the principal place of trade in Ireland, and has increased in wealth and population with great rapidity. In 1758 the number of looms was 399. The spinning of cotton by machinery was introduced in 1777, and of linen in 1808. In 1838 there were 50 steam-engines of an aggregate of 1274 horse-power engaged in the spinning of linen and cotton yarns. In 1841 the number of steam-mills for spinning linen yarn was 25; one of which employed 800 persons; and since then the number and extent of the mills has greatly increased. In 1792 ship-building was first commenced here: there are now four large ship yards in full employment. The registry of shipping belonging to the port, the arrival and departure of laden ships, the quantity of imports and exports, and the amount of customs' revenue, have all increased with great rapidity during the last few years.

The manufacture of linens, damasks, and diapers is carried on in all its branches with great activity. In the ornamental wrappers alone in which the linens are made up for the foreign market, a sum of 80,000*l.* a year is said to be expended. In cottons the principal articles manufactured are velvets, fustians, jeans, ticking, ginghams, quiltings, calico muslins. Calico printing is carried on extensively at Whitehouse, and there are in the town and vicinity numerous dye-works, bleach-works, and print fields. The total number of spindles employed in the linen and cotton factories was computed in 1837 at 982,000. Since that time the number has probably increased more than half. There is also a very large trade in cured provisions. In the town and vicinity are several extensive foundries and machine-making establishments, where all kinds of steam-engines and mill machinery are made. Orders have recently been executed at the iron-works of Messrs. MacAdam for St. Petersburg and Cairo.

The Royal Society for the Promotion and Improvement of the growth of Flax in Ireland has its office in Belfast. It was established in 1841 by some Belfast merchants, who perceived the great importance of providing the market in Ireland and Great Britain, with a home-grown article, instead of purchasing it as heretofore from abroad at an annual average cost of 6,000,000*l.* A staff of agriculturists trained in the most approved methods of management is retained by the society, and sent to give instructions to all parts of Ireland where there are farming societies or landed proprietors subscribing to the society's funds. The cultivation of the flax-plant has by this means been largely introduced into many parts of the country where it was previously unknown. The recent important experiments concerning the growth and manufacture of flax are likely to be of great moment to Belfast. The School of Design, at Belfast, is one of the most flourishing in the three kingdoms. In the middle of 1850 the number of pupils was no less than 148, many of whom are designers for damask weavers and muslin embroiderers.

Few towns in the empire have entered with more earnestness than Belfast into the principle and details of the Industrial Exhibition of 1851. A managing committee has been chosen, and local juries are to be formed for selecting the specimens to be exhibited. The flax fabrics generally are to be divided by the Belfast Committee into three classes. 1st. Plain linens, and lawns. 2nd. Damasks, diapers, drills, and other twilled linens. 3rd. Cambrics, printed linens and cambrics, and handkerchiefs—plain, bordered, embroidered, printed, and dyed. Each class is to contain specimens bleached, unbleached, and dyed. There will also be a very rich exhibition of Irish produce from Belfast.

BELI'ZE, or BALIZE. [HONDURAS.]

BELFRY, that part of a church-tower or steeple in which the bells are hung. In constructing a belfry, the frame-work is placed either on stone corbels, or is made to bear on a recess formed in the wall. The higher the bells are placed in the tower, the more does the vibration, caused by ringing them, affect the masonry.

BELGIUM. The coal-fields of this important country are in the provinces of Limbourg, Liége, Namur, and Hainault; and many of them are very rich in produce. The other varieties of mineral produce include iron, calamine, and building stone.

The soil, which in each of the provinces consists almost entirely of clay and sand, has for the most part been rendered fertile by a due admixture of both these elements. Agricultural industry is carried to a great extent in the kingdom, and the cultivators have availed themselves of every advantage within their reach for increasing their productions. The most general objects of cultivation are wheat, rye, barley, oats, meslin, buck-wheat, hemp, flax, madder, hops, chicory, colza, and the artificial grasses, clover, trefoil, lucerne, and sainfoin. The ruta baga, or Swedish turnip, turnips, carrots, parsnips, and potatoes are raised to a considerable amount by field culture. Tobacco is grown in some situations, and everywhere fruits of the kinds grown in England are objects of careful cultivation. Turf-ashes and drainage refuse are much more largely and advantageously used as manure in Belgium than in England. Among the timber trees are the oak, chestnut, horse-chestnut, beech, elm, horn-beam, ash, walnut, fir, and different descriptions of poplars.

The manufacturing industry of Belgium has declined in modern times as compared with the extent to which it was carried on in the 14th century. The making of thread-lace, originated in Flanders, and up to a comparatively recent period Brussels and Mechlin carried on a large trade in that article: in the former city more than 12,000 persons were once employed for its production. Early in the 14th century, Louvain contained 4,000 looms for woollens; and Brussels and Antwerp had together as large a number. At a date not quite so remote, Ghent employed between 30,000 and 40,000 looms for the weaving of woollen and linen goods. It is mentioned that the weavers of that city once mustered 16,000 men in arms under the banners of their respective trades. The woollen manufacture is now prosecuted at Verviers, Charleroy, Tournay, Mons, and some other towns. Cotton-spinning and weaving are carried on in some of the larger towns. Liége and Maastricht contain large tanneries. At Antwerp, Ostend, and Ghent, there are some sugar refineries; cutlery is made at Namur; and fire-arms in considerable quantities at Liége. Breweries are numerous and extensive in most of the principal towns throughout the kingdom. Earthenware is made of good quality in several places; and the manufacture of nails has been carried on for a very long period in the provinces of Liége and Hainault.

The articles which Belgium supplies to England are oak-bark, flax, madder, clover seed, spelter, and sheep's wool; in return for which we send various kinds of East India and West India produce, tobacco, and cotton wool, besides British and Irish produce and manufactures, consisting principally of brass and copper manufactures, cotton manufactures and yarn, hardware, earthenware, salt, sheep's wool, woollen and worsted yarn, and woollen manufactures. The exports of British produce and manufactures to Belgium have averaged about one million sterling annually for the last six or eight years; but in 1849 they reached nearly a million and a half.

In no continental country, except France, are such extensive preparations being made to assume a creditable position at the Great Exhibition of 1851, as in Belgium. The whole of the great towns will contribute their choicest productions. Of the industrial exhibitions of Belgium, we have spoken in the INTRODUCTION.

BELGOROD, or BJELGOROD, the chief town of a circle in the Russian province of Kursk, has several manufactories for refining and pressing wax, and for spinning and weaving; and it carries on a considerable trade in hemp, bristles, honey, wax, leather, soap, &c.

BELGRADE, the capital of the principality of Servia in Turkey, is the principal entrepôt of the trade between Constantinople and Saloniki on one side, and Vienna and Pesth on the other. The exports consist of wool, dressed skins, buffalo and cow hides, wax, honey, tan-bark, silk, oxen and cows, immense numbers of pigs, and firewood. From Hungary, hardware, delft, porcelain, pottery, and salt are imported; and from Semlin the city is supplied with wheat, flour, oats, meat, vegetables, and fruits. There is considerable manufacturing industry among the inhabitants. Carpets, silk and cotton stuffs, arms, and leather are manufactured, and there are several bell foundries in the town.

BELL. Bells of a small size are undoubtedly very ancient; the Hebrews, the Greeks, and the Romans used them. The large bells now used in churches are said to have been invented by Paulinus, bishop of Nola in Campania, about the year 400; and they were probably introduced into England very soon after their invention.

The city of Nankin in China was anciently famous for the largeness of its bells, but they were afterwards far exceeded in size by those of the churches in Moscow. A bell given by the czar Boris Godunof to the cathedral of Moscow weighed 288,000 pounds, and another given by the Empress Anne, probably the largest in the known world, weighed 432,000 pounds. According to Coxe the height of this last bell was 19 feet, the circumference at the bottom 63 feet 11 inches, and its greatest thickness 23 inches. The great bell of St. Paul's weighs between 11,000 and 12,000 pounds. The new 'Great Tom of Lincoln,' cast in 1835, weighs 12,000 pounds; the 'Great Tom of Oxford,' 17,000 pounds; and the great bell cast in 1845 for York Minster, the heaviest in the United Kingdom, upwards of twelve tons, or about 27,000 pounds. The most ponderous bell ever cast in this country was, we believe, that made by Messrs. Mears in 1843 for the Roman catholic cathedral at Montreal.

The tone of a bell depends conjointly on the diameter and the thickness; a small bell or a thick bell giving, relatively, a more acute tone than one which is either larger or thinner. Hence the founder regulates the diameter and thickness according to the musical pitch of the tone which the bell is to yield; but, as this cannot be rigidly attained by casting only, the bells (say a set to form chimes) are attuned by chipping away some of the metal with a sharp-pointed hammer; reducing the diameter at the lower edge when the tone is too low, and reducing the thickness at the part where the hammer strikes when the tone is too acute.

Some of the recent parlour or table bells are not only convenient but very elegant productions. In Mr. Furlong's registered table-bell, which is quite ornamental enough to take its place among other adornments of the table, we have only to press down a little button or knob at the top, when a sound is produced loud enough to be heard in a distant room. The knob acts upon a small spring which moves a hammer.

It has been suggested that a single bar of well-made cast steel would be the cheapest of all bells for small churches, on account of its sonorous quality. There remains the consideration, however, how far such a substance would bear blows without fracture.

The casting of large church-bells is a process requiring great care and attention. Messrs. Mears, of Whitechapel, have for many years manufactured nearly all those made in this country of large dimensions. The operations are briefly described in a later article. [Founding.]

BELL-METAL. [Alloy.]

BELPER, Derbyshire, is one of those towns which owe their rise and importance to the cotton manufacture. Its prosperity is of modern date, and is to be principally ascribed to the establishment of the cotton works of Messrs. Strutt. It is now one of the most flourishing towns in Derbyshire. The chief manufacturing establishments are Messrs. Strutt's, who employ upwards of 2000 persons in the various departments of the cotton manufacture; Messrs. Ward, Sturt, and Sharp, manufacturing hosiers; and Messrs. Brettle, also manufacturing hosiers. This hosiery work is mostly carried on at the houses of the operatives. The manufacture of nails is carried on to some extent at Belper. There is also an extensive manufactory of brown earthenware near the town. Seams of coal are worked in the neighbourhood.

BELVEDERE, in Architecture, is a small building constructed at the top of a house or palace, and open to the air, at least on one side, and often on all. The term is an Italian compound, signifying 'a fine view;' and in Italy it is constructed expressly for that purpose, combined with the object of enjoying the cool evening breeze. The most celebrated construction of this kind at Rome, which is in the Vatican, was built by Bramante in that part called the Court of the Belvedere. Belvederes are not uncommon in France; but the term is applied rather to a summer-house in a park or garden, than to the constructions on the tops of houses.

BENCOOLEN, a settlement in the possession of the Dutch on the Island of Sumatra, has many spice plantations, which are cultivated by slaves under the superintendence of the Dutch. Bencoolen trades with Batavia, Bengal, the Coromandel coast, and the more northern ports of Sumatra. The imports are chiefly cloths, rice, salt, opium, tobacco, sugar, and European manufactures.

BENGAL. The province of Bengal is poor in mineral productions. The hills in Silhet produce iron ore. Iron is made at Punduah by a curious process, which at once smelts the ore and renders it malleable. Granular iron ore of the fineness of sand is washed clean and mixed with water into a soft mass; bits of reed, sticks, or leaves are then dipped in it, and take up as much as they will hold, and these, when pretty dry, are thrown into the top of a small clay cupola furnace and melted. It appears from this detail that the ore must possess a great degree of purity. The ore might be collected in large quantities, and as limestone of good quality and coal are found in the same range of hills the smelting might be easily effected. Some petroleum springs exist in the same district. Coal is abundant also in the Jungle Mahals, whence it can be easily conveyed to Calcutta in the rainy season, down the Dummoodah river. Coal and iron ore are both of them procured in Birbhoom, and iron works have long been carried on there by the natives. Extensive forests occur in the neighbourhood of these works, and the smelting is performed by means of charcoal.

The external commerce of Bengal is of great magnitude In the year 1831-2, under the regulated commerce during the existence of the trading privileges of the East India Company, the amount of the imports into Bengal (exclusive of the trade with China) was close upon two millions sterling; of the exports about 3,380,000*l.* The imports, by the year 1842, rose to nearly 6,000,000*l.*, and the exports to more than 8,000,000*l.* In 1846 the number of British ships entered inwards at Calcutta was 1080, of foreign ships only 99; in the same year there cleared outward 725 British ships, and 114 foreign ships.

The whole of these vessels had an average tonnage of about 300 tons.

A considerable part of the trade between Bengal and China is carried on from Calcutta. The most valuable part of this trade as regards its amount, is the shipment of opium. It formed more than one half of the value of the cargoes sent from the different presidencies to China, but the recent treaties with that country have considerably altered the trade in that article. The present value of opium exported from India amounts to upwards of 3,500,000*l.* The other principal articles shipped from Bengal to China are saltpetre, pearls, carnelians, coral, woollen and cotton manufactures of Europe, and rice.

The trade of Bengal with England comprehends an immense variety of objects. The principal articles of import are various metals, foreign wine and spirits, beer, woollen and cotton cloths, cotton yarn, glass, and hardware; in return for which the exports are, silk and silk manufactures, indigo, sugar, saltpetre, and lac-dye. Of these articles indigo is by far the most important, its value being equal to nearly one-half the total exports to Europe from the province. It is principally cultivated in Moorshedabad, Nuddea, and Jessore in Bengal, and Tirhoot in Bahar, where there are altogether from 300 to 400 factories in operation. The cotton exported is not so much from Bengal as from other provinces. With the exception of the districts on the eastern frontier, silk is grown in every part of the province of Bengal, and forms a considerable part of its exports; nearly the whole quantity of raw silk that is shipped is sent to England, which likewise receives more than half of the silk fabrics exported from the province. Saltpetre is another article of importance. Nearly seven-eighths of the whole quantity shipped from the province come to Great Britain. This branch of trade is valuable, from its furnishing a material part of the freight of homeward bound ships, the weight and bulk of saltpetre being great in proportion to its money value, while the opposite condition holds with regard to the greater part of the productions of India.

From France Bengal receives wine and brandy; the returns are principally made in saltpetre and indigo. To Portugal cotton piece-goods form the principal export; the imports consist almost wholly of bullion and wine. A large part of the trade of Portugal with China has been carried on intermediately through Calcutta, where the Portuguese traders take in opium and cotton, the returns for which go direct from Canton to Portugal, or to the transatlantic possessions of that country. A trade nearly similar in its character has been kept up between Bengal and Brazil, since the political separation of the latter country from Portugal. The United States of America take from Bengal silk, piece-goods, and indigo, with some other articles of Indian produce to a small amount; and send in exchange specie, metals, manufactured goods, and ice.

Bengal exports to Java piece-goods and opium, and receives in return copper, Banca tin, pepper and spices. To Manilla cotton piece-goods are sent; the returns are copper and silver from the South American mines, and a few trifling articles of fragrant woods and spices, the produce of the Philippine isles. From the Coromandel coast chank shells are brought, to a considerable value. These shells are employed by the Hindoos in their religious worship, and are cut into bracelets or worn round the ancle: payment for them is usually made in rice, and European goods. Ceylon supplies Bengal with cocoa-nut oil, coir, a few pearls, some spices, and chank-shells; in return for piece-goods, sugar, silk, and rice. Teak timber, sandal-wood, coir, cocoa-nuts, and drugs, are received from Malabar; which takes in payment piece-goods, metals and British woollens, with dates, raisins, coral and pearls. From the shores of the Persian Gulf Bengal receives Persian copper, almonds, dates, coffee, gums, pearls, coir, cocoa-nuts, pepper, and bullion; the returns are made in cotton piece-goods, silk goods, indigo, sugar, and grain. With the Mauritius, Bengal exchanges rice for pepper and spices. With the Moluccas and other eastern islands Bengal carries on a considerable trade. From the Burmese empire Bengal imports timber, gold and silver treasure, wax, sapan-wood, ivory, and drugs; and exports thither British cotton goods, grain, indigo, sugar, and opium.

It is expected that a few productions from this far distant region will grace the Industrial Exhibition of 1851.

BENZO'IC ACID. This acid, as its name imports, is usually obtained from the resinous substance called *gum benzoin* or *benjamin;* it occurs also in some other vegetable bodies, as the balsam of Peru and of Tolu, storax, and the flowers of the *trifolium melilotus officinalis.* It is found also in the urine of some animals.

The properties of benzoic acid are, that when pure it is colourless; it crystallizes in soft and rather elastic crystals, which have scarcely any smell; its taste is rather aromatic and penetrating than sour; by exposure to the air it undergoes no change; it combines readily with alkalies, and earthy and metallic oxides, forming salts which are called *benzoates;* it fuses and sublimes at a gentle heat, but a part of it is decomposed by the process; if strongly heated, it takes fire and burns with a bright yellow flame.

The saline compounds of benzoic acid are not very important. In its medical uses, the sublimed acid is the best form. It occurs in white needle-like prisms, with a silky lustre, a peculiar odour, and a pungent taste. It enters into the composition of the *Tinctura Camphoræ Composita* of the 'London Pharmacopœia,' and the *Tinctura Opii Ammoniata* of the 'Edinburgh Pharmacopœia,' two preparations long known under the name of *paregoric elixir.*

BENZOIN, or BENJAMIN, a resinous substance commonly but improperly termed a gum. It is extracted from the *Styrax Benzoin*, which grows in Sumatra, by making incisions in the trunk. It hardens very quickly, and is imported in the state of brittle masses, which when fractured present a mixture of white, brown, and red grains, frequently as large as an almond. Its smell is agreeable, resembling that of vanilla. It melts at a moderate heat, and yields benzoic acid, of which it contains about eighteen per cent. It contains, besides benzoic acid and a little volatile oil, three different resins, the separation of which requires complicated chemical processes.

In its medicinal action benzoin resembles the other balsamic resins, being stimulant and exciting. It is chiefly employed to yield benzoic acid, and as an ingredient in pastiles, or to burn in censers in Roman Catholic churches. It enters into the composition of the *Tinctura Benzoini Composita.* A solution of benzoin in alcohol, added to twenty parts of rose water, forms the cosmetic called *Virgin's milk.*

Gum benzoin is rather an expensive article. Its present price is about 50*l.* per cwt.

BENZOLE LIGHT. The Benzole light, introduced in 1849 by Mr. Mansfield, is founded on an ingenious mode of combining air with the vapour of a volatile liquid. Benzole is a compound of hydrogen and carbon, procured in considerable quantity from coal tar. Mr. Mansfield's plan consists in conducting a stream of atmospheric air or of common gas through a reservoir charged with benzole. The benzole vaporizes very rapidly; and in so doing, it combines with the air or gas, and produces a mixture well fitted for artificial illumination. Benzole and other hydro-carbons, when used in lamps in the usual way, contain too much carbon to burn satisfactorily; and means have long been sought to obviate the difficulty, by mixing the vapour of these substances with any gas or air which contains less carbon, or by mixing two liquids together before the vaporization of the hydro-carbon. A gallon of benzole is said to be equal in light-giving power to a thousand cubic feet of coal gas. The method is intended to be applied both on a large and on a small scale.

BE'RBERIS, a genus of plants containing many useful species. The fruit of the *Berberis aristata* and *B. Nepalensis* is dried by the mountaineers of India as raisins, and sent to the plains for sale. The bitterness and astringency of the bark has caused them to be received into the list of useful medicinal plants. The *Berberis vulgaris*, or Common Barberry, appears to inhabit equally the north of Europe, Asia, and America, in woods and thickets, especially in limestone countries. It is usually a bush from four to six foot high; but in Italy it becomes as large as a plum tree, living a couple of centuries or more. The wood is hard, but brittle, and is chiefly employed by the dyers for staining yellow.

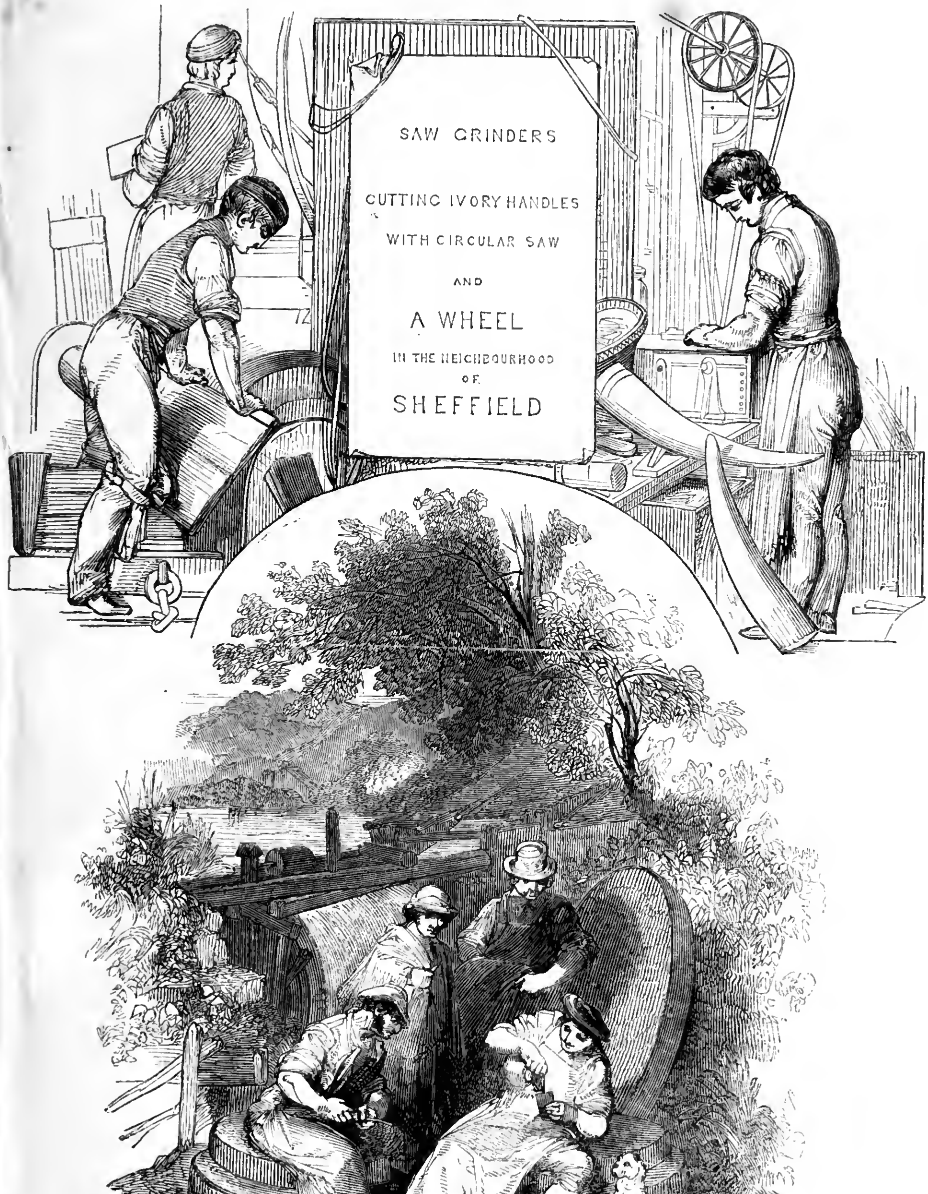
BERBICE. [GUYANA.]

BERGAMO, a province of Austrian Italy, is in many parts very fertile; and the system of irrigation is extensively applied. The vine, the olive, and the walnut are cultivated, and there are large plantations of mulberry-trees, raising silk, which constitute the chief wealth of the country. There are also valuable iron mines, large iron-works, and several woollen and silk-factories in the province. In the chief town, Bergamo, is *La Fiera*, a vast quadrangular building, with three gates on each side, courts and streets within, and contains 600 shops, in which the various manufactures of Lombardy and other provinces of Austria are exposed for sale, at an annual autumnal fair. Goods are sold at this fair to the amount of 1,000,000l., about one-third of which is laid out for silks.

BERGAMOT, ESSENCE OF, an essential oil, obtained both by pressure and distillation from the rind of the Bergamot, the ripe fruit of the *Citrus Bergamium:* it is limpid, yellowish, and fluid. The kind procured by pressure is not so fluid as that yielded by distillation, but its odour is more agreeable. The smell resembles that of oranges, and it is used as perfume.

About 22,000 lbs. of Bergamot oil was imported in 1848.

BERGEN, a town in the kingdom of Norway, on the sea-coast, has a commerce of



KNIGHTS CYCLOPÆDIA
OF THE
INDUSTRY OF ALL NATIONS

No. 10

much magnitude. The northern provinces receive from Bergen the greater part both of the necessaries and the luxuries of life. In return, Bergen receives from these provinces large quantities of fish, herrings, roes, fish-oil, tallow, skins, feathers, &c., all which articles are brought by the Nordlandmen themselves in their own vessels to Bergen. They come to Bergen twice a year with their own yachts, which form a peculiar class of merchant vessels. The arrival at Bergen of the fishing-vessels from the Lofoden winter fisheries occasions extraordinary life in the port and on the quays; the harbour is almost blocked up with vessels; frequently the whole night is employed in transporting, packing, and preparing goods; so that this season may be considered as a continual fair.

The trade of Bergen with the other parts of Norway is by no means so important as that with Nordland. From the interior of the country Bergen receives iron-manufactures, glass, tiles, &c.; from the towns in the diocese of Trondjem, some copper, with millstones and grindstones.

Of foreign trade, that with the Baltic is very considerable. Bergen exports thither large quantities of herrings and other fish, and skins, receiving in return hemp, glue, hops, canvas, linen, &c. The trade with Denmark, Hamburg, Holland, England, Sweden, France, and the Mediterranean, is extensive: the produce and manufactures of those countries being received in exchange for the fish and other produce of Norway. Bergen is, in fact, the Liverpool of Norway.

BERLIN, the metropolis of the Prussian monarchy, and the largest and finest town in Germany, (Vienna only excepted) cannot be otherwise than an important commercial and industrial centre. Among the six *quartiers*, or quarters, and the five suburbs, of which the city consists, are many manufacturing establishments of great magnitude. In the Berlin Quarter are the *Lager* house and the royal *Gewerb* house, where several royal manufactories are conducted on a large scale. In the new Cologne Quarter is the Royal Salt Magazine. In the Friedrichswerder Quarter is the Royal Foundry. In the Friedrichstadt Quarter is the Royal Porcelain Manufactory; and the royal manufactory of gold and silver work. The celebrated Berlin iron trinkets are manufactured near the Oranienburg Gate.

Berlin is one of the first manufacturing towns in the Prussian dominions. Its chief productions are the celebrated Berlin china, silks, silks and cottons mixed, woollens, cottons, stockings, and ribands; and next in order are gunpowder, cast-iron ware, silk hats, paper, oils, refined sugars, and tobacco and snuff.

If war should not unhappily step in to check industry, Berlin will be well represented at the Hyde Park Exhibition of 1851. Its iron, porcelain, terra cotta, silks, woollens, linens, paper, and machinery, are all to be illustrated by choice specimens. The Berlin castings are especially looked forward to with interest. Casting in zinc, an art not much practised in England, is carried to much perfection in Berlin; cast groups in this material, the size of life, are to be forwarded to England. In terra-cotta and earthenware the Berlin manufacturers are endeavouring not merely to attain high artistic excellence, but also to produce good and cheap articles for every day use.

A very interesting feature, in relation to the Industrial Exhibition, is the formation of a committee at Berlin, for facilitating the visit of a large number of Prussians to London in 1851. Contracts are to be made with railway companies, and with steam-boat and omnibus proprietors; dwelling-houses and a dining-hall are to be engaged; and all expenses from Berlin to London, in London, and from London back to Berlin, are to be charged to each visitor in one sum.

BERLIN WORK. [EMBROIDERY.]

BERMUDAS. These islands grow the palm-tree, the leaves of which are exported to be made up as ladies' fans. Coffee, cotton, indigo, and tobacco, are no longer cultivated, with the exception of a little indigo; the soil appears to have become less suitable than formerly for the production of these articles. The principal employment is the building of vessels, which are generally small, swift, and very durable, being constructed of cedar. Plaiting of straw, and of the mid-rib of the palmetto leaf, is also carried on; and a beautiful species of white freestone, easily cut, is exported to the West Indies for ornamental architecture. Vessels annually visit the Bahamas for salt.

Bermuda is one of the naval and military depôts of Britain. Plans have been recently drawn up for a new steam factory, storehouses, hospitals, workmen's dwellings, &c. Upwards of 300,000*l.* were spent in the public works between 1838 and 1848; of this 157,000*l.* were for a breakwater. The Government are about to build a hauling-up slip. The new victualling-office is planned to contain one year's stores for 5000 men. The new steam factory has been formed in order to facilitate the repairs when needed of the Atlantic steamers. The vessels belonging to the Bermudas in 1848 were 56, of 3645 tons burden. The imports in 1848 were of the value of 149,000*l.*; the exports 18,000*l.* The British produce and manufactures sent to Bermuda in 1849 were valued at 47,138*l.*

BERN, the largest and most populous canton of Switzerland, produces corn, though not sufficient for the consumption of the population, and fruit in abundance, especially apples, pears, plums, nuts, and cherries. From the cherries the spirit called *kirschwasser* is made, which, as well as the extract from absinth, or wormwood, are articles of common use, as in the rest of Switzerland. Beer and cider are made in the country. The vine thrives in a few districts, chiefly in that of Nidau near the lake of Bienne, where wine is made. Hemp and flax are also among the products of the soil; but cattle and the products of the dairy constitute the chief wealth of the country; cheese is made in abundance for exportation, especially in the valleys of Emmenthal, Simmenthal, and Gessenai or Saanen.

The canton of Bern is, to a moderate extent, a manufacturing country. Linen is made in many places, sufficient for the internal consumption: there are tanneries at Bern, as well as a few manufactories of silks, coarse woollens, and paper. Mathematical instruments, watches, and jewellery, muskets, and other arms, are made at Bern, Porentrui, &c. The Bernese gunpowder is excellent, and far superior in quality to the French: the manufacturing of it is free, and not subject to monopoly as in France. At Correndelin, Untervilier, and other places in the valleys of the Jura, there are iron-works and foundries, the iron ore being found in abundance in the mountains. Timber for building and fuel are supplied by the mountain forests, and from other woods in several parts of the lowlands.

The chief town, Bern, is rather a centre for the general commerce of the country, than a manufacturing place.

BERTHOLLET, CLAUDE LOUIS, must be briefly noticed in this place, for the services which his chemical discoveries rendered to manufactures. Shortly before the first French revolution, he was appointed superintendent of dyeing processes, which office had been occupied by Macquer. To this appointment chemistry was indebted for his work on dyeing, which contains a better account both of the theory and practice of the art than any work which had before made its appearance. When the French Revolution broke out, and that country became involved in war, many of the requisites for carrying it on which had previously been imported could no longer be obtained through this channel. This was especially the case with saltpetre for the manufacture of gunpowder. In this emergency Berthollet visited almost every part of the country, for the purpose of pointing out the means of extracting and purifying this salt; he was also employed with some other men of science, in the processes of smelting iron and converting it into steel. In the year 1792, being appointed one of the commissioners of the mint, he introduced considerable improvements into the processes employed in that establishment.

BERWICK-UPON-TWEED. From the reign of Edward I. to that of Elizabeth, the principal export trade of Berwick was wool, wool fells, hides, and salmon: but the trade of the place has suffered some modification in later times. The principal manufactures are those connected with shipping; but there are also iron-foundries, and steam-engines; sacking, cotton hosiery, damask, diaper, carpets, hats, and shoes are made. Until within the last thirty-five years, a highly lucrative trade was carried on in the export of pork and eggs to London, the annual value of the eggs shipped being at least 30,000*l.*, and of pork about 10,000*l.*; but since the peace this trade has totally ceased, and the metropolis is supplied from Ireland and the Continent. Berwick is now a bonding port. The existing trade of the town is principally confined to the exporting of salmon, corn, aud coals to London, to various ports in Scotland, and to foreign countries. Of late considerable quantities of ale and whiskey have been shipped to London. The smacks and small brigs which formerly carried on the trade of the place have been superseded by large and well fitted schooners, and clipper ships. There are regular traders between Berwick, London, Kingston-upon-Hull, Newcastle-upon-Tyne, and Leith. About 70 vessels belong to the port.

The salmon fisheries in the Tweed have for many centuries been very productive. Until about the year 1790 the salmon sent from Berwick were either salted and dried, or boiled and pickled with salt and vinegar, except salmon-trout, which were occasionally kept alive in wells or tanks in the ship's hold. The exports were principally to London, but considerable quantities of salted salmon were also sent to the Mediterranean. At present the whole are sent fresh to London packed in ice. About 800 of the inhabitants of Berwick are now (1850) employed in the fisheries.

BERYL, a mineral species, among the varieties of which are found two of the most beautiful and costly gems with which we are acquainted, namely, the *emerald* and the *precious beryl.* The species belongs to the rhombohedral system of crystallization, usually occurring in regular hexagonal prisms. Its constituents are silica, alumina, glucina, lime, and oxides of iron, columbium, and chromium, in proportions which differ in different specimens.

The two chief varieties, emerald and aquamarine or precious beryl, differ chiefly in colour; the term emerald being applied to those possessing the peculiar rich deep green so well known as the emerald green; while all the other varieties are comprehended under the name of beryl: those which are clear, transparent, possess a good colour, and present various shades of sky-blue or mountain-green, being the aquamarine or precious beryl. The colour of the emerald is attributed to a small quantity of green oxide of chromium; while the varieties in the tints of beryl may be considered to be produced by admixtures of the oxides of iron, the yellow being the colour of the peroxides of iron, and the mountain-green and the various shades of blue being the effect of varying quantities of the protoxide.

Emeralds, for the last two centuries, have rarely been found, except in Peru, where they occur in Santa Fé and in the valley of Tunca. Those met with in modern times seldom exceed the size of a walnut. Beryls are procured from Siberia, Brazil, Sweden, Saxony, Bohemia, and Iceland. The beryl sometimes occurs in crystals of very large size. The value of the emerald depends not only on its size, colour, and brilliancy, but also on its being free from flaws, by which this gem is frequently greatly deteriorated in the eye of the jeweller.

BESANCON, the capital formerly of Franche-Comté, is a place of considerable manufacturing industry; its position on the Doubs, which is navigable, and on the canal which unites the Rhone and the Rhine, makes it the centre of an important trade. The chief manufacture is that of the works of watches and clocks, in which 2000 men are employed. Hosiery, coarse woollens and cottons, carpets, room-paper, hardware, stoves, liqueurs, and artificial flowers, are manufactured. There are also iron-foundries, china-works, tanneries, several large breweries, and establishments for bleaching wax. The trade of the town consists in its industrial products, and in wine, brandy, broad-cloth, groceries, iron, and coal.

BETEL-NUTS. These nuts are procured from the *Areca Catechu*, a palm which grows in India. They have an astringent flavour; but when mixed with lime, and with the leaf of the betel pepper, they become milder, and are chewed by the natives of India.

BEVEL, or BEVIL, is the name applied both to the oblique angle formed by two surfaces which meet at either more or less than a right angle, and to the instrument employed by carpenters and joiners for taking and transferring such angles. The common carpenter's bevel consists of a straight wooden stock, mortised at one end to receive a thin blade, which is usually formed of steel, and attached to the stock by a pin in such a way that it may be turned to any required angle, and secured by a tightening screw. Where many articles have to be worked to the same angle, it is desirable to use a fixed bevel, made to the required angle, especially where one or both of the limbs are curved.

BIDEFORD. This town, one of the most active in Devonshire, has long had a considerable foreign trade. The principal imports are timber from North America; timber, hemp, and tallow, from Russia and Norway; fruits, wines, and brandies, from Spain, Portugal, and the Mediterranean; and general goods from Ireland. The exports are oak-bark, which is shipped in considerable quantities to Scotland and Ireland; earthenware, tiles, &c., to Wales, Guernsey, and Jersey; linen and woollen goods, cordage, iron, naval stores, provisions, &c., to the North American colonies. Corn is largely exported to the Metropolis, and to the ports along the coast. About 150 vessels belong to the port. In recent years there have been about 800 arrivals and departures of vessels annually. Ship building is carried on at Bideford to a considerable extent. There are several potteries, principally for the manufacture of flower-pots. A manufactory of coarse china and earthenware has been lately established at a short distance from the town. Clay of a good quality is found on land in the neighbourhood belonging to Lord Clinton. Anthracite or culm is found in the vicinity in sufficient quantity to be worked for economical purposes.

BIGA, a chariot or car drawn by two horses. The Romans had also their quadrigæ, and sometimes their sejuges, septim-juges, &c.; and Suetonius says that Nero, when he was a performer in the Olympic games, made use of a decem-jugis, a chariot drawn by ten horses.

BILBA'O, one of the chief towns of Spain on the Biscayan coast, has an active population, who are employed in agriculture, commerce, and the manufacturing of iron. There are also manufactures of paper, hats, soap, leather, earthenware, and cigars.

The principal articles of exportation are wool and wheat to foreign countries, and iron to other parts of the Peninsula.

BILL OF LADING, is an acknowledgment

signed usually by the master of a trading ship, but occasionally by some person authorised to act on his behalf, certifying the receipt of merchandise on board the ship, and engaging under certain conditions and with certain exceptions, such as 'the act of God,' the 'king's enemies,' &c., to deliver the said merchandise safely at the port to which the ship is bound, either to the shipper, or to such other person as he may signify by a written assignment upon the Bill of Lading.

BILLON, in coinage, is a composition of precious and base metal, consisting of gold or silver alloyed with copper, in the mixture of which the copper predominates. The word came to us from the French.

BILSTON, Staffordshire, owes all its importance to the introduction of the iron works. It previously consisted of only a few private houses; but standing in a district which possesses considerable mines of coal, iron-stone, quarry-stone, and clay, it has rapidly increased in extent and population. The manufacturing industry is very great. There are numerous furnaces for smelting iron-ore, with foundries, forges, slitting-mills, steam engines, and the various works necessary for the preparation of iron. The manufacture of tin, and of every kind of japanned and enamelled wares, with that of iron, from nails and wire to the heaviest and bulkiest articles, is largely carried on at Bilston. At night there are upwards of fifty furnace fires and coke heaps sending forth their bodies of flame in and near the town. Coarse pottery is made with the clay which is found in the neighbourhood in much abundance. There is also here a deep orange-coloured and almost impalpable sand, which is much used in the casting of metals; the neighbourhood is likewise noted for a stone quarry.

BINGLEY is one of the remarkable clothing towns of West Yorkshire. The manufacture of worsted yarn is carried on to a considerable extent in the town and neighbourhood, besides which there are very extensive cotton-mills; there are also paper manufactories; and there is some trade in malt. Altogether Bingley has become a place of much manufacturing and commercial importance.

BINNACLE, a kind of box used on board ship to contain the compass. *Bittacle*, an abbreviation of the French word *habitacle*, a small habitation, was the original form of the word. Many improvements have been made in the binnacle within the last few years; chiefly in relation to the mode of throwing light upon the compass card in the night.

BIRCH. The birch is extremely valuable among our forest trees, from the variety of materials which it furnishes to the manufacturing arts. The common birch is one of the hardiest of known trees, and flourishes best in cold countries. The timber, without possessing any one quality in an eminent degree, possesses many qualities in a very useful degree. It is employed in France for the felloes of wheels; and in Russia for the construction of small rustic carriages. On many parts of the continent it is used for many articles of furniture, cooperage, and turnery, and sabots or wooden shoes. The Highlanders of Scotland use birch for so many purposes that they are said to, 'make everything of it;' they build their houses of it; make their beds, chairs, tables, dishes and spoons of it; construct their mills of it; make their carts, ploughs, barrows, gates, and fences of it; and even manufacture ropes of it. The above uses apply to the *white* birch. The *black* or *canoe* birch is also of great value; it flourishes in North America, and is there applied to numerous purposes: some specimens of the timber are so beautifully grained that they are cut into veneers and used in cabinet work. The wood of the *tall* or *American* birch is used in the United States and Nova Scotia for yokes of cattle and frames of sledges, for hoops of casks, for articles of furniture, and for many other purposes. The wood of the *pliant* birch has a fine and close grain, a considerable degree of strength, and takes a brilliant polish. It is used in the United States for tables, bedsteads, arm-chairs, sofas, coach-panels, shoe-lasts, and a great variety of purposes.

The *bark* of all the species of birch is of very considerable value, especially in cold northern countries, where it is applied to a great variety of uses. It is very durable, and little acted on by air or water. In some countries it is used as a coping for walls and a covering for roofs. The bark of large trees is cut by the Laplanders into pieces large enough to form capes or short cloaks. It is also employed for boots, shoes, baskets, boxes, mats, cordage, harness, and thread. In Kamtschatka the inner bark is dried and ground, and mixed with oatmeal to form an article of food; and the same people eat the bark in small pieces with the roe of fish. It is much used for tanning leather; and a yellowish brown dye which it yields is employed in some countries for dyeing woollens and rein-deer skins. The bark of the *canoe* birch is used in America for roof coverings, baskets, boxes, portfolios, paper, and inner soles of shoes; but it is more extensively employed in making the canoes of the *voyageurs*, engaged in the fur-trade of Canada: such a canoe, capable of accommodating four persons will weigh no more than forty lbs. Tents are also made of this bark. The bark of the *tall* birch is used in tanning; that of the *pliant* birch is stripped white in the green state, by the Kamtschatkadales, cut into narrow strips like vermicelli, and stewed with caviare.

The *branches* and young *shoots* are also of much value. They are made into hoops, brooms, faggot-ties, baskets, hurdles, cream-whisks, and similar articles—including the well-known rod of our old-fashioned schoolmasters. The Alpine mountaineers make torches of them. The Laplanders construct tents with birch branches covered with turf. In the Scottish highlands the branches are employed as fuel in the distillation of whiskey, being found to impart a flavour to it which enhances its value; they are similarly employed for smoking hams and herrings. The young branches of the *dwarf* birch furnish beds and fuel to the Laplanders; and those of the *black* birch are employed in the United States for making hoops for rice-casks.

The *leaves*, *catkins*, and other green parts, have also their value. The leaves are eaten by goats and rabbits. A yellow colour is obtained from them, useful in painting and dyeing. The Finlanders use the dried leaves as tea. The buds and catkins afford a substitute for bees' wax. A bed stuffed with birch leaves is said to be useful to rheumatic persons by promoting perspiration. The leaves of the dwarf birch yield a peculiar kind of fungus, from which the *moxa* or *amadou* is prepared, and which the Laplanders employ as a medicine in many painful diseases; and its seeds afford nourishment to the ptarmigan or white partridge, a very important bird in Lapland.

The *sap* of the birch is made to yield beer, wine, spirit, vinegar, and sugar, according to the mode of treatment; the tree being tapped to allow the sap to flow or ooze out. Birch beer is made by fermenting the sap with yeast, hot-water, and hops; birch wine is made by boiling the sap with sugar or honey, and fermenting, clarifying and flavouring in various ways; but spirit is made by distillation; birch vinegar by allowing the acetous fermentation to supervene on the vinous; and birch sugar by boiling and evaporating the sap.

To complete the catalogue of the use of the birch we have to mention the *fuel*, the *ashes*, and the *oil*. The wood gives a bright and ardent flame, and is much employed for smelting iron in France, Russia, and Sweden—its charcoal burns a long time, and is in much demand for making gunpowder and black crayons. The ashes are rich in potash. An oil, much used in Russia, is obtained by burning birch bark in close receptacles.

BIRD'S-EYE VIEW, a mode of perspective representation, in which the objects are drawn as seen from above. Thus, if a hole were bored through the ceiling of a lofty room, a person looking down through it would have a proper bird's-eye view of the apartment and its furniture. But the most common mode of giving a bird's-eye view differs from ordinary perspective only in the horizontal line, and consequently the point of sight, being placed considerably above the objects represented. The scene is thus shown as it would appear from some lofty station, as a tower or other eminence.

BIRD-LIME, a glutinous vegetable product, obtained principally from the inner bark of the holly, or from the berries of the misletoe, but also from other plants. It is prepared from the holly bark by bruising, long boiling in water, and fermentation; the mass is again boiled in water, and evaporated to a proper consistence. In different countries various processes are employed. When properly prepared from the holly it is of a greenish colour; its smell resembles that of linseed oil; its taste is bitter; it is adhesive, tenacious, and may be drawn out into threads.

BIRKBECK, GEORGE, M.D., one of the warmest friends and kindest instructors of the operative classes, was born in 1776, at Settle, in Yorkshire, where his father was a merchant and banker. He displayed an early predilection for mechanical and scientific subjects, which led him to select the medical profession as his pursuit. While at Edinburgh, he was put in nomination for the professorship of the Andersonian Institution at Glasgow, and his election was carried by a considerable majority. In November 1799 he commenced his first course of lectures at Glasgow on Natural and Experimental Philosophy. Some time afterwards he commenced a gratuitous course of lectures, which he continued until 1804, when he relinquished the professorship, and was succeeded by Dr. Ure.

While in active practice in London as a physician, Dr. Birkbeck had few opportunities of following up the labours which he had commenced at Glasgow for the advancement of scientific knowledge amongst artisans; but it was a subject which he had always at heart. In 1820 he gave a gratuitous course of seventeen lectures at the London Institution. In 1827 he was the chief means of promoting the first *Mechanics' Institution*. He presided at a public meeting at the Crown and Anchor, which was attended, amongst others, by Dr. Lushington, Jeremy Bentham, David Wilkie, and Cobbett; and after another meeting, on the 2nd of December, the first officers of the 'London Mechanics' Institution' were appointed on the 15th of December. Dr. Birkbeck was elected president, which office he filled till his death; and his son has since been annually elected to the same post. At the formation of the institution, Dr. Birkbeck generously lent the sum of 3,700*l.*, for the purpose of building a lecture-room, &c.

Dr. Birkbeck's professional and scientific pursuits, and his services in various ways, in connection with objects of public utility, were continued to the last; and those who attended the lectures at the London Mechanics' Institution, in its best days, will well remember those of Dr. Birkbeck as among the most instructive and the most attractive. He died December 1, 1841, at his residence in Finsbury-square, London.

BIRKENHEAD. The grand undertakings at this town are among the most remarkable commercial phenomena of our age. The overflowings of Liverpool commerce are to form the basis of Birkenhead commerce.

The rapid growth of Birkenhead is entirely owing to the formation of commodious docks. In 1842 the town commissioners were empowered by act of parliament to purchase the manorial rights, &c., pertaining to the ancient ferry at Woodside, which is the nearest ferry to Liverpool; and in 1844, under another act, they purchased Monk's Ferry. In 1844 they obtained an act of still greater importance, under which a tidal basin, docks, and other extensive accommodations for trade and shipping are now in progress. The magnitude of these works may be inferred from the following abstract of their cost, which is taken from the estimates: New market, 20,000*l.*; town-hall, 10,000*l.*; park, 25,000*l.*; docks in Wallasey Pool, 400,000*l.*; dock warehouses (by a private company), 600,000*l.* The design of converting Wallasey Pool, on which Birkenhead is situated, into docks, was entertained several years ago, and originated with the late Mr. Laird; but it was not until 1844 that an act, as already mentioned, was obtained for effecting this object. The first stone of the proposed docks was laid on the 23rd of October, 1844. The area of the principal or floating dock will be 120 acres, a space exceeding that of all the docks in Liverpool, and it will have 19 feet depth of water. It will be surrounded with quays, warehouses, and other conveniences for shipping and discharging cargoes. There will also be a tidal harbour of about 40 acres, accessible at all times by the largest steamers employed in the coasting trade, and by all vessels whose draught does not exceed 15 feet; a harbour of refuge with an area of 10 acres; and beaching-ground of 4 or 5 acres, for the free use of the river craft.

A certain clashing of interests between different governing bodies at Birkenhead, has rendered new arrangements frequently necessary. Besides the act of 1844, a second was obtained in 1845 for the formation of dock and wharf walls; and another in 1847 for new powers in respect to these constructions. In 1848 an act was passed for the formation of a board of trustees of the Birkenhead docks, which board (in order to represent and reconcile conflicting interests) is to be formed as follows:—Four trustees chosen by the bondholders, with whose funds the docks were in part constructed; four chosen by the Birkenhead commissioners; and three by the Wallasey commissioners.

There has recently (1850) been an act passed, which relieves the commissioners from a very onerous engagement with the Woods and Forests department; and the dock-works have recommenced (after some delay) with great vigour. Three thousand men are now employed; forty-five acres of dock are nearly ready for the reception of shipping; and the whole are expected to be finished in 1851.

Birkenhead is connected by railway with Chester, and thence with all parts of England; and a branch to Warrington, recently opened, has shortened the distance between Birkenhead and Manchester. The rails are brought round all the quays of the docks. Hitherto the trade of Birkenhead has not reached the point which had been anticipated, and the hope of which had led to such extensive and costly works; but whenever a large traffic shall grow up there, it will be well accommodated by the railway, the docks, and the warehouses, all of which are admirably planned to work together in one system. It is expected that the coasting trade and the steam-packet trade will be those which will first seek accommodation at Birkenhead.

BIRMAH. The Birman empire is rich in mines of gold, silver, copper, tin, lead, antimony, and iron, but they are much neglected by the natives. Many kinds of precious stones are obtained by digging and washing the gravel in the beds of rivulets or small brooks. The varieties said to exist are, the oriental sapphire, the oriental ruby, the opalescent ruby, the star ruby; the green, the yellow, and the white sapphire; and the oriental amethyst. Noble serpentine or green-stone, is found in most of the upper branches of the Irawaddi, and exported in considerable quantities by the Chinese to their own country, where it is used for rings and amulets. Mines of amber are found on the branches of the Kyan-Duayn, and in the vicinity of the Bhanmò. Coal seems to be plentiful, but it is not used. Limestone exists in great abundance in the mountains near the capital; and statuary marble is also met with. Nitre, natron, and culinary salt, are found in many of the arid and calcareous tracts in the upper provinces, and chiefly in the neighbourhood of the capital. Natron, in an impure state, is used by the natives instead of soap, a preparation with which they seem to be unacquainted. Salt is extracted from some lakes in the upper provinces, especially near Monchabo, and from the sea water in the lower provinces.

Among the vegetable productions of the Birman forests the teak holds the first place. The plants which become articles of commerce in the country include bamboo, catechu, sugar, tea, cocoa, tobacco, cotton, indigo, and betel.

The progress of the Birmans in the useful arts has not been great. All their cotton fabrics are coarse and high-priced, and British piece-goods are imported in considerable quantity. Silk articles, coarse and unglazed earthenware, iron implements, muskets and swords, and gold and silver ornaments, are manufactured, mostly in a rude style.

The commerce carried on in the interior of the country is considerable; the different portions of the empire producing several things which are not found in others. The inhabitants of the sea-coast and the lower country carry to the capital and the upper provinces rice, salt, dried fish, and foreign commodities; which are paid for by the produce of the interior. The foreign commerce, chiefly with China, is conducted principally at two annual fairs, at Bhanmò and Midé. The Chinese arrive with laden horses, mules, and asses; bringing with them an immense assortment of goods.

BIRMINGHAM, is in many respects the most remarkable of our manufacturing towns. It dates its productive industry from early times. Being situated at a moderate distance from the Staffordshire iron mines, which were unquestionably worked at a very early date, and placed in a district which was distinguished as woody (the northern or Arden division of Warwickshire), it offered great facilities for smelting the ore of iron, which, before the introduction of the steam-engine, could only be effected by means of charcoal. The iron being prepared on the spot, it is natural to suppose that a colony of artificers would settle here, and that they would early acquire skill in the use of the material. In the time of Leland, Birmingham was inhabited by 'smiths, that use to make knives and all manner of cutting-tools; and many lorimers that make bitts, and a great many nailors.' A place thus characterised by the industry and ingenuity of its inhabitants, waited only for more favourable circumstances to increase its wealth. This change appears to have taken place in the 17th century, when, on the restoration of Charles II., a fondness for metal ornaments was introduced from France, where the exiled king and his adherents had long resided, and Birmingham took the lead in the manufacture of the glittering trifles which the taste of the age demanded.

Camden, who travelled through England in the 16th century, a few years after Leland, says of Birmingham, in his 'Britannia,' that 'most of the inhabitants be smiths;' to which Bishop Gibson, in his edition of Camden, published in 1722, adds, 'and other artificers in iron and steel, whose performances are greatly admired both at home and abroad.' The editor was, however, scarcely correct if he meant it to be understood that the manufactures of the town were in his time confined to iron and steel goods. Various fancy articles in other materials were then regularly made, and the manufacture of brass goods had commenced. The use of this valuable compound metal has continually increased during the last hundred years, and the talent of the designer has been tasked in the invention of new forms, and in the adaptation of classical models to the purposes of modern domestic comfort and ornament. The introduction of the stamp especially, which was first applied to the multiplication of copies of smaller wares, as buttons, buckles, and cloak pins, and which was at length adapted, by increasing its power, to the production of large forms, has caused the greatest change in this branch of manufacture. There are establishments in Birmingham which have from two to three hundred thousand dies employed in stamping

In plated wares the style and form were long deficient in grace, but the taste and spirit of Messrs. Boulton and Watt were instrumental in improving the forms of the articles usually produced; and an increasing familiarity with antient models, and with the florid and playful style of the age of Louis XIV., continues to give new impetus to this manufacture. The introduction of the new mixture called Albata, or British plate, was the forerunner of a very large branch of manufacture at Birmingham. The convenient material called Britannia metal is also largely manufactured here.

The founding of iron is rapidly improving and extending itself in this town. A comparatively few years ago the principal cast articles of this material were heavy kitchen articles grates and stoves; but increased care in the selection of the metal, and a desire to produce elegant forms at a cheap rate, have caused cast iron articles to be manufactured of small size and of light and tasteful patterns, which, when coloured by bronzing, almost equal the more expensive brass wares; and in hollow vessels such perfection in thinness and lightness is attained, that the use of beaten copper is almost forgotten. The iron-work of Mr. Paxton's Palace of Industry has been prepared under the direction of the eminent Birmingham firm of Fox and Henderson.

The manufacture of guns was introduced at the commencement of the last century, and has been carried on to an immense extent; nearly 5,000,000 of fire arms were supplied from Birmingham between the years 1804 and 1818 inclusive, to meet the demands of government and of private trade. A proof-house, under the conduct of a master, wardens, and trustees, was established by act of parliament in 1813 where the fabric of all guns and pistol barrels is tried by a heavy charge: all those which sustain the explosion receive a stamp, to counterfeit which is felony; and to sell such barrels without the stamp is punishable by heavy fines. There is also a government proof-house for the ordnance department, a comprehensive and interesting establishment near the Walsall Road, at the northern end of the town.

Buttons and buckles, so far as they are articles of ornament, almost took their rise in Birmingham, and this town witnessed all the fluctuations of these manufactures, from the small plain buckle, and the horn or bone button coated with metal foil, through all the capricious and almost innumerable varieties of form and ornament which prevailed during the age of powder, embroidery, and gold lace, or which the still more fantastic taste of foreign markets demanded. At length the buckle has been completely supplanted by shoe-strings, and the button has undergone great changes: moulds of wood or horn being now very generally covered with silk or some other woven material, as a substitute for the metal button. The button factories are among the largest establishments in Birmingham. The denomination of 'The toyshop of Europe,' given to Birmingham by Burke, was correct at the time, but the extensive application of powerful mechanical forces has now raised the character of the staple productions of the place. All articles of metallic ornament, such as polished steel toys, gold and gilt jewellery, chains, snuff-boxes, &c., are still manufactured, but not to such an amount as to form a preponderant part of the industry of Birmingham.

The quantity of silver used in the manufacture of pencil-cases, boxes, chains, thimbles, &c., and in the numerous fittings and mountings attached to glass and other wares, is considerable, and an assay office is established in the town, where all articles in this metal being above five dwt. are examined, and if found to be of the proper standard, are marked with the government stamp. The use of gold and silver has greatly increased in Birmingham in recent years. The process of electro plating has given rise to a wholly new department of manufacture, of which Birmingham is the chief seat.

Japanning in all its varieties, is another extensive branch of manufacture. It commenced with the varnished boxes and small articles, which were coarse imitations of the Oriental toys, but the art was gradually improved by John Taylor, who gave elegance to the devices on the surface; and still further by Baskerville, who introduced the light and highly polished but firm and durable *papier mâché*, which he adorned with paintings in a style before unknown. This branch of industry has called forth great talent; and some of those who have taken rank among the painters of their age have commenced their career by executing the ornamental designs on the trays and waiters of Birmingham. Articles of this kind are susceptible of great elegance, and when produced in perfection are beautiful specimens of the pictorial art. In all the recent Exhibitions of Manufactures in this country the *papier mâché* of Messrs. Jennens and Bettridge and other manufacturers at Birmingham, has been remarkable for its artistic beauty.

Glass making has long been carried on in Birmingham. This manufacture is not now confined, in its higher branches, to cut vessels for the table, nor to the sparkling drops which decorate girandoles and chandeliers; but glass for ornamental purposes is cast into forms of scrolls, foliage, busts, and well-formed complete figures of small size. Window-glass is also made in large quantities. Messrs. Chance's glass works, among the largest in the world, are at Birmingham; it is here that the glass for the Industrial Palace has been made.

An apparently trivial article, the steel-pen, has latterly grown into such extensive use as to form a considerable branch of manufacture. The price has been perpetually diminishing, and the article itself, at the same time, continually improving. This manufacture was first established in Birmingham in 1821, before which time the article was scarcely known in the market. Shortly after this date they sold for 12*s.* per dozen, but the price rapidly fell to 2*s.* per dozen, or 1*l.* 4*s.* per gross. The increasing facilities of production, and the consequent abundant supply, added to the competition of the numerous manufacturers, has since gradually lowered the price to 6*d.* a gross, or even less. There is one establishment in Birmingham (besides others of less extent) where many hundred millions of pens are made annually, and where 300 persons are employed.

The cutlers, lorimers, and makers of wrought nails, who in Leland's time formed the bulk of the industrious population of Birmingham, have thus been gradually driven away by the increasing demand for articles requiring more taste and skill in design and execution. Agricultural and manufacturing steel and edge tools, including files and saws, are however still made, and numerous new manufactures have been introduced during the present century, which owed their origin to the facilities afforded by the newly created mechanical forces, that gave a spur to invention by almost insuring its success. Among these are wire-drawing, cut-nail, screw, and pin manufacturing. Fine turnery naturally arose from the increasing use of the lathe. Die-sinkers, modellers, and designers were required by those who used stamps and casting-moulds; and engravers were called for to represent in the books of patterns exhibited by the merchants the forms of the numerous articles prepared by brass and iron-founders and other manufacturers. Artists in these several lines have been thus drawn to the place, and the arts themselves are here cultivated to a degree of perfection before unknown out of the metropolis.

The establishment of gas companies gave an impetus to the manufacture of tubes of various descriptions, as well as to the taste of the designer in forming graceful combinations. One of the most complete establishments in the town, the Cambridge Works, comprising long ranges of newly-built premises, is devoted to the making of all kinds of furniture in which brass tubing can be employed.

Some branches of the cotton manufacture have been localized in Birmingham, such as those of webbing for braces and girths, cords, lines, &c., probably on account of the facility with which the requisite machinery can be procured.

The umbrella trade arose from the demand for the brass furniture of these useful contrivances, which led to an attempt to execute orders for the articles complete. This attempt has been so successful that many thousand operatives are now engaged in the Birmingham umbrella trade.

In the nail manufacture as carried on in Birmingham, machinery is used by which well-formed nails are cut out of sheet-iron, with a rapidity which leaves far behind the swiftest motion of the muscles in snipping paper with scissors. There is one very large establishment, filled with machines for making nails by steam-power, where from one to two thousand millions of nails are made in a year. Screws are also formed with beautiful precision without heat, and by a series of mechanical contrivances which remove the severity of the labour, and render the attention and superintendence of women and children nearly sufficient.

Steam-engines are now very numerous in Birmingham. Their number was estimated in 1849 at 5,400 horses' power, consuming about 380 tons of coal per day, and equalling the labour of 86,400 men.

There are few large factories, properly so called, in which an article goes through the entire range of manufacturing processes; but there is a vast number of workshops, more or less extensive, in each of which portions of the work are done. One manufactured article, which is sold retail for a penny, may go through 20 workshops before it is finished; some having 40 or 50 workmen, some 4 or 5, while some are simply the garrets of workmen, who ply their trade each by his own fireside. With the exception of the metropolis, there is perhaps no town in England where there are so many persons combining in themselves the characters of master and workman, as Birmingham, and none in which there is more observable a chain of links connecting one with another.

The School of Design is rendering much service in Birmingham. The classes have been well filled from the time of their establishment; and it is found that boys who have attended those classes are sought after by manufacturers in preference to those who have not had such training. During 1850 there have been about thirty pupils in the modelling class alone: a branch of study peculiarly important in a town where so much metal casting is carried on. Some time elapsed before the Birmingham manufacturers fully appreciated the necessity of cultivating the arts of design, as a means of competing with France in productions of taste; but this necessity is now well understood, and rapid advances are being made in the right direction.

Near Birmingham were the celebrated Soho Works. These works were built by a native of Birmingham, Matthew Boulton, and ten years afterwards, in 1774, Watt entered into partnership with him. During the remainder of the century, the Soho Works produced those numerous steam-engines which became the marvel of all Europe. But it was not merely the making of steam-engines and other large pieces of machinery that made these works famous; other manufacturing processes were introduced; or, more properly speaking, other manufactures preceded that of steam-engines by a few years. Buttons, buckles, watch-chains, and trinkets, were the first objects of manufacture; then plated ware; then or-molu vases, candelabra, clock cases, and watch stands; then pure silver plate of the highest order of excellence. Among the various processes carried on at Soho, perhaps none has attained a more extended celebrity than the application of steam to coining; the engine for this purpose was erected by Boulton in 1783, but subsequently received great improvements. The Soho factory has been recently abandoned; and the Soho or Aston estate has been offered for sale to the town authorities, to form a People's Park for Birmingham.

Of all the towns in England, perhaps, excepting the metropolis, Birmingham could present the greatest variety of manufactures to the Exhibition of 1851; and it is on all accounts to be hoped that that town will be worthily represented. There are understood to be about 300 Exhibitors from Birmingham, who will illustrate between 40 and 50 different branches of manufacture, and will occupy about 25,000 square feet of exhibition space. All the chief departments of Birmingham industry will be represented.

BISCAY. The commerce carried on in the harbours of the Bay of Biscay is considerable. Spain, however, furnishes only a small portion of the exports, owing to the difficulty of transporting heavy commodities to the coast from the interior. From the inland provinces only wool is brought to the ports of Santander and Bilbao; the produce of the coast itself is not considerable, and consists chiefly of fruits. But more than half the products of the soil of France, and nearly the same portion of its manufactures, are exported from the harbours of Bayonne, Bordeaux, Rochelle, Nantes, Vannes, and Orient; and large quantities of foreign merchandise are received by the same ports.

BISCUIT, a kind of bread usually made in the form of flat cakes, and pierced with holes, to insure the complete evaporation of moisture in the baking, which is necessary for preserving it during long voyages. Biscuits are used on land as a kind of luxury, but at sea they are an article of the first necessity, since bread, in the more ordinary form in which it is used on shore, would speedily become mouldy and unfit for food. The name biscuit (twice-baked), is evidently derived from the nature of the processes to which this kind of bread was formerly subjected. The two bakings then used are no longer found necessary; but the name, although thus rendered inappropriate, has been continued. The same name is applied, inappropriately also, to several articles made by confectioners, such as sponge biscuits, Naples biscuits, &c., which are sweetened with sugar, and are not reduced by baking to the state of dryness which is a necessary quality of biscuits in their ordinary form. Biscuits for use as ship-bread are usually made of the meal of wheat from which only the coarsest bran has been separated. The process of mixing, kneading, stamping, and baking by hand were brought to an almost machine-like degree of rapidity and regularity in the great biscuit-manufactories established by government for supplying the British navy; but of late years they have been still further perfected and facilitated by the introduction of machinery, by which the dough is thoroughly mixed and rolled out into sheets about two yards long and one wide, which are stamped at one stroke, into about sixty hexagonal biscuits of about six to the pound, in such a manner as to leave the sheet sufficiently coherent to be put into the oven as one piece, though when baked the biscuits are easily separated. The hexagonal shape has been substituted for the circular, because it effects a saving of time and material, and also of space in packing.

At the ship biscuit bakery of Mr. Harrison, at Liverpool, an apparatus has been constructed which exceeds in automatic completeness even that employed at the government establishments; for the made biscuits travel into the oven without the aid of any *peel* or other hand-worked tool. The flour and water are placed in a cylinder, mixed well together by revolving bars, kneaded by a large iron cylinder, and spread like a large sheet on an endless cloth. As this cloth travels along, a nicely adjusted piece of mechanism cuts the dough into the shape of six-sided biscuits, and stamps them. Passing along the endless cloth, the biscuits are received by a kind of gridiron and enter the oven. This oven is 26 feet long; it is heated by hot water, and bakes the biscuits as they slowly travel through it. The mechanism was patented by Mr. Harrison in 1849.

BISCUIT, in pottery, is a term applied to articles which have been only once baked or burnt, and have not yet received the glaze or vitreous coat, with which most articles of porcelain or earthenware are covered. The name appears to be given on account of the resemblance of such wares in colour and texture to ship-bread. Biscuit-ware is permeable to water, which, however, it imbibes without undergoing any alteration of texture; and owing to this quality it is used for vessels in which fluids are cooled by evaporation from the outer surface. Statuettes of great delicacy are now made of this material.

BISMUTH. The minerals in which this metal constitutes the principal ingredient are comparatively few in number. *Native or Octahedral Bismuth* occurs in opaque crystals, having a metallic lustre, and a reddish silver-white fracture. *Bismuth-ochre* is a straw-coloured mineral, consisting of an oxide of the metal. *Bismuth-glance* is a lead-gray-coloured mineral, occurring in four-sided prisms, having a metallic lustre; it is a sulphuret of the metal.

The pure metal, bismuth, was first shown to be a peculiar one by Stahl and Dufay: this metal generally occurs native, sometimes combined with sulphur, but rarely with oxygen, in Saxony, Bohemia, and Transylvania. It is largely produced at Schneeberg, in Saxony, to the extent of 10,000 lbs. per annum. Bismuth is of a reddish-white colour; its lustre is considerable, and its structure lamellated: it is so brittle as to be easily reducible to powder when cold; it melts at about 470° or 480°. At a high temperature this metal is volatilised, may be distilled in close vessels, and solidifies in foliated crystals; if it be merely melted in a crucible and cautiously cooled, it crystallises in well-defined cubes.

Bismuth and the metals generally combine to form alloys, and it frequently renders the metal with which it unites more fusible. Potassium, sodium, arsenic, antimony, and tellurium, all form alloys with bismuth. It imparts brittleness to copper, silver, tungsten, palladium, rhodium, gold, and platinum, when alloyed with them. With mercury it forms a very fluid alloy. Newton's fusible metal is composed of eight parts of bismuth, five of lead, three of tin; this alloy melts at 212°. Rose's alloy is still more fusible; it is made of two parts bismuth, one lead, and one tin; it fuses at about 201°.

Bismuth and Acids combine to form salts of bismuth, many of which are used in medicine and the arts. Bismuth is principally employed for the purpose of making fusible alloys and as an ingredient in solders. It is often called in the arts *tin-glass*. For medicinal purposes, the subnitrate or *magistery* of bismuth is sometimes employed. The cosmetic termed *pearl white*, or *Spanish white*, is subnitrate of bismuth.

BISON. This fine animal is much valued by the North American Indians: among whom the flesh is in great request, and is prepared in various ways. The tongue is accounted an especial delicacy; and the hump, or rather the flesh on the long spinous processes of the anterior dorsal vertebra, forming the withers, is accounted excellent. Much of the bison meat is made into *pemmican* for keeping, and a good bison cow furnishes dried flesh and fat sufficient to make a bag weighing ninety pounds. A fat bull has yielded a hundred and fifty pounds weight of tallow. The Indians dress the skins generally with the hair on; they serve as blankets and warm wrappers, and are sold for a considerable sum. The fleece is also useful, and is spun and woven into various articles. Dr. Richardson informs us that some of the bison wool has been manufactured in England into a remarkably fine and beautiful cloth; in the colony of Osnaboya on the Red River, a warm and durable cloth is formed of it. The horns are converted into powder-flasks.

BISTRE, a brown pigment made of the soot of different kinds of wood, but that of beech is generally preferred. The soot of the burned wood is sifted, steeped in water, decanted, and dried, to obtain a pure clean powder. Bistre is not used in oil painting, but produces the same effect in water-colours as brown pink does in oil.

BITTERS, a collective term applied to those vegetable substances the most prominent sensible quality of which is *bitterness*. It was at one time attempted to refer this quality to an hypothetical principle, which was termed *bitter principle;* but it was soon perceived that substances having a bitter taste were indebted for it to very different sources. A certain quantity of bitter matter seems to promote the digestion of all food; hence bitter substances are found abundantly distributed in the vegetable kingdom. Where there is a deficiency of bitter matter, and the food is of a very watery kind, such as grows in wet pastures, cattle are known to suffer from various diseases, especially from the rot. The best known bitters, perhaps, are quassia, wormwood, aloes, chamomile, colocynth, gentian, hop, rhubarb, rue, trefoil, and briony. *Bitters* is also the name for a class of beverages. The Swiss peasant, inhabiting high stations on the Alps, which are almost constantly wrapped in a thick and penetrating mist, uses a spirit distilled from gentian, called *bitter snaps*. In the West Indies, where languor of the system, with weakness of the digestive organs, is produced by the excessive heat, the appetite is restored and the stomach invigorated by taking before dinner a few drops in a glass of water of an elixir made of gentian, serpentaria, orange-peel, and sweet flag-root; and in America the infusion or tincture of serpentaria is sometimes taken every morning in damp aguish situations to prevent intermittents. In England, the "bitters" of the spirit shops are made of brandy, orange-peel, gentian, cassia, cloves or some other spice, sugar, and one or two other ingredients.

BITTERSPAR is a crystallized mineral, sometimes colourless, but frequently presents tints of pink, yellow, brown, and green, derived from the presence of iron and manganese. It possesses various degrees of transparency, and has a somewhat pearly lustre, whence it has been called pearlspar.

BITUMEN. A considerable number of combustible mineral substances are sometimes arranged under the head of bitumens; but their properties vary greatly in some respects, as, for example, with regard to solidity, fluidity, and colour. The term bitumen is however usually applied to two varieties, a harder kind called asphaltum [ASPHALTUM], and a softer kind called elastic bitumen. Naphtha is a fluid kind, and petroleum semi-fluid.

Elastic bitumen, sometimes called fossil caoutchouc, is a rare mineral product. It is found in the Odin mine, near Castleton, in Derbyshire; in a coal-mine of Montrelais, a few leagues from Angers, in France; and in a coal-mine near South Bury, in Massachusets, United States.

Elastic bitumen is brown or blackish brown, translucent in small portions, soft and elastic like caoutchouc, but sometimes hard as leather. Its density varies from 0.9053 to 1.233. It fuses readily, and at a higher temperature it takes fire and burns with a sooty flame. It is but slightly soluble in alcohol, but readily in potash.

According to the analysis of M. Henry, jun., the elastic bitumen consists of

	English.	French.
Carbon	52.250	58.260
Hydrogen	7.496	4.890
Azote	0.154	0.104
Oxygen	40.100	36.746
	100.	100.

In Texas there has recently been discovered a bituminous lake very similar to that of Trinidad. It is situated in Jefferson county, about 100 miles from Houston. It is about a quarter of a mile in circumference. In the summer months there is a spring near the middle of the lake where an oily liquid like petroleum continually boils up from the bottom; this liquid gradually hardens on exposure to the air, and forms a black pitchy substance. It burns, when lighted, with a clear bright light, but gives out a very pungent odour. During the winter the bitumen in the lake presents a hard surface, and is covered with water having a somewhat sour taste.

BLACK LEAD. [PLUMBAGO.]

BLACKBURN. This is one of the great cotton manufacturing towns of Lancashire. As far back as 1650, one particular article of the staple trade of the county was produced here with better success than in any other place. It was known by the name of 'Blackburn checks,' and was a species of cloth consisting of a linen warp and cotton woof, one or both of which being dyed in the thread, gave to the piece when woven a striped or checked appearance. This fabric was afterwards superseded by another, 'the Blackburn grays,' so called because the materials of which it was composed were not dyed, but sent to the printers unbleached, or as it is technically described, in the gray state, in order to have the patterns stamped upon them. In the history of the improvements by which the manufacture of cotton has been brought to its present state of perfection, it appears that several improvements of considerable importance owe their discovery to the ingenuity and talent of natives of this town. Among others the invention of the crank and comb for taking the carding from the cylinder of the carding-engine, undoubtedly belongs to James Hargrave, a working carpenter of Blackburn. His patent was one of the earliest that was taken out for the construction of the spinning-jenny. But, for a long period, the chief article manufactured here was calicoes, for which the Blackburn weavers were celebrated. This branch of trade is now transferred to the power looms, and the remnant of hand-loom weavers are chiefly employed in making low-priced muslins.

According to statistics recently furnished to us, there are now (1850) from 50,000 to 60,000 pieces of cotton goods manufactured each week in Blackburn and the vicinity, on which above 10,000 persons are employed. The annual value of the goods produced is supposed to exceed 2,000,000*l*. About 100,000 spindles are employed in cotton-spinning, producing about 100,000 pounds of yarn weekly, at 40 hanks to the pound. The power-looms and woven fabrics of Blackburn will be illustrated at the Industrial Exhibition.

BLACK SEA. This important sea was an emporium of commerce in very early times. The Greeks, and more especially the Ionian Greeks of Milétus, formed numerous establishments along its shores, from which they exported slaves, cattle, and corn in great quantities. The shores were pretty well known to the Romans. In the times of the Byzantine emperors, Constantinople drew from it a considerable part of its provision; and in the twelfth century the Genoese formed some establishments on its north-eastern coast, and carried on a very active commerce overland with India. When the Turks acquired power in this quarter, the trade of this sea declined, but the rise of Russian power on the northern shore gave a new impulse to it. At the present time the number of Greek vessels is by far the greatest in this sea. They export the corn, hides, timber, iron, and furs of Russia, and import wine, fruits, and the manufactures of England and France. Between the northern and southern shores of the Black Sea the commercial intercourse is not great, the produce of the Anatolian shores, which consists of grain, timber, and copper, not being in demand in Russia, which exports the same commodities. There are very few fisheries carried on in this sea.

BLADDERS, when brought to a clean and prepared state, are especially useful to druggists, oilmen, colourmen, and other manufacturers, as coverings for various kinds of vessels; they derive their value from their thinness, toughness, and impermeability to water. The bladders of the ox and other animals, when deprived of bits of loose membrane and other impurities, are washed in a weak solution of chloride of lime; then rinsed in clean water; then blown out and submitted to pressure by rolling them under the arm, which stretches and enlarges them; then blown out quite tight, and fastened and dried.

BLASTING has long been practised as the most efficient mode of removing or detaching heavy masses of rock in mining operations, and, by reason of recent improvements, has become one of the most important resources of the civil engineer. The old method of blasting rocks consisted in drilling or boring a hole to a considerable depth with suitable instruments, depositing a charge of gunpowder at the lower or farther end of the hole, and then filling up, or 'tamping,' the remainder of the hole with clay, or some other soft mineral substance, well rammed, to make it as tight as possible. A wire laid in the hole during this operation was subsequently withdrawn, and a train of gunpowder inserted in its place; and this train, and consequently the blast itself, was fired by a slow match (often consisting simply of brown paper smeared with grease), intended to burn long enough to allow the person who fired it to reach a place of safety. Many accidents have arisen from the uncertainty of this process, the risk of which has however been lessened by the substitution of copper for iron in the 'needle' by which a passage for the train is formed. Beckford's 'safety fuse,' too, is a great improvement; it consists of a small train of powder inserted in a water-proof cord, which burns at so steady and uniform a rate, that by cutting it to a suitable length any desired interval may be secured between the lighting and the explosion.

The great improvement of modern times however consists in the employment of a galvanic current to ignite the powder,—an arrangement which renders premature explosion next to impossible. A galvanic current, so long as it passes along an uninterrupted wire, is perfectly harmless; but if its course be interrupted by breaking the continuity of the wire, intense heat, sufficient to ignite powder, is produced. In addition to the superior safety and certainty of this mode of firing, it has the advantage of being applicable under water as well as on land, and, by its perfectly instantaneous action, of enabling the engineer to fire as many blasts as he may desire at one operation, so as to accomplish, by their joint action, effects otherwise unattainable.

Colonel (now General) Pasley first employed galvanism in submarine blasting in 1839, in his successful operations on the wreck of the Royal George at Spithead. Shortly afterwards galvanic blasting, both on land and under water, was practised both in America and in Scotland; but it was in January 1843 that Mr. William Cubitt commenced, on the works of the South-Eastern Railway, the stupendous operations which established its capabilities on a scale never before attempted. He began by throwing down, by three simultaneous blasts, consuming together about 18,000 lbs. or more than eight tons of gunpowder, a bulky promontory called the Round Down Cliff, between the Abbot's Cliff and Shakspere tunnels, near Dover. By this operation, which was attended with very little noise, a cliff nearly 400 feet high was thrown down, and no less than 400,000 cubic yards of chalk were distributed over the beach, covering an area of 18 acres to an average depth of 14 feet; and it was computed that 7000*l.* and six months' time were saved to the company. Several smaller operations followed this great experiment, in one of which twenty-eight blasts were arranged to explode simultaneously, although from some derangement of the wires a few failed. The same agency has since been extensively employed elsewhere, especially at Seaford in 1850.

The latest invention relating to blasting which requires notice is the substitution of gun-cotton for gunpowder, which bids fair still further to diminish danger and to increase the certainty of the operation. From experiments tried early in 1847, at the Standege tunnel, on the Huddersfield and Manchester Railway, and on the works of the Birmingham, Wolverhampton, and Stour Valley Railway at Birmingham, it appears that the effects of the gun cotton is, weight for weight, from three to five times as great as that of gunpowder; so that a much smaller bore will suffice for the blast, and it may be, with equal labour, carried down much deeper into the rock. A still more important difference is, that the gun-cotton produces no smoke, so that the workmen may resume their labours immediately after the explosion, instead of having to wait several hours, and sometimes a whole day, as when gunpowder is used. The cotton also produces much less noise and vibration, and is considered far less liable to accident in removal from place to place than gunpowder.

BLAST FURNACE. [FURNACE.]

BLEACHING is the whitening of fibrous materials used as clothing. Wool and silk, cotton and flax, the substances most usually submitted to this process, contain certain colouring matters which, though natural, are not essential constituents; and these colouring matters are more readily acted upon by chemical agents, and suffer decomposition with greater facility than the animal and vegetable substances with which they are combined; so that they may be removed with little or no injury to the texture of the articles, thereby increasing their beauty, and fitting them for the processes of the dyer and calico-printer.

Bleaching is a very ancient process, and was practised especially in Egypt, but probably in a very simple and tedious way; the process, perhaps, consisting of little more than exposure to air, light, and moisture. The art was scarcely known in Great Britain until about a century since, it having formerly been usual to send brown Scotch linen to Holland to be bleached, where it was done by steeping several days in a solution of potash, and subsequently for nearly a week in butter-milk, and then spreading it out upon grass for some months. One of the first improvements on this tedious process was the introduction, about the middle of the last century, by Dr. Home, of Edinburgh, of dilute sulphuric acid in lieu of sour milk, by which the process, which formerly occupied from six to eight months, was reduced to four months, the acid being as effectual in one day's application as the milk in six or eight weeks. This improvement was eclipsed by the application of chlorine, formerly called dephlogisticated marine acid, or oxymuriatic acid, which was discovered by Scheele about 1774. Berthollet suggested its application to bleaching in 1785, in a paper read before the Academy of Sciences at Paris; and from him the process was shortly afterwards introduced into Scotland by Watt. About the same time Mr. Thomas Henry, of Manchester, introduced the process in Lancashire; and to these two gentlemen belongs the credit of perfecting and applying in this country a process whereby as much bleaching is as well performed in a few hours, within a space a few hundred yards square, as on the old process would have required weeks of exposure upon a hundred acres of land. The chlorine was first used in a state of simple solution in water; but chloride of lime, commonly called *bleaching powder*, for the manufacture of which Mr. Tennant, of Glasgow, obtained a patent in 1799, is now almost universally employed, especially in the bleaching of cotton. Sulphurous acid gas, or the fumes of burning sulphur, is also often employed in bleaching wool and silk, as well as straw and feathers. Wax is usually bleached simply by exposure to air, light, and moisture.

Scarcely a year elapses without developing some new processes or apparatus for bleaching, which are made the subjects of patents, though not always with advantage to the patentees. M. David, of Paris, took out a patent in 1849 for a peculiar mode of applying chlorine to the goods to be bleached. The chemical materials for making the gas are to be provided by the bleacher; and as the gas is generated, it is conveyed by pipes into a close chamber. The woven goods are to be laid on perforated shelves in this chamber, and thus be acted on by the chlorine. A fan or blowing machine is used to clear the chamber of gas before the goods are removed from it; and glass windows are provided to the chamber, through which the process may be watched. Messrs. Cocksey and Nightingale, in the same year patented an apparatus to be used in bleaching, dyeing, or sizing; it consists in a peculiar way of conducting the cloth into and through a vessel of liquid, and beating it on both surfaces immediately after its emersion; so that the fibres become impregnated, and the superfluous liquid driven off. A third patent in the same year, by Mr. Thom, relates to a mode of causing the woven goods to pass over two rollers, one above another, in a close chamber filled with chlorine or sulphurous acid gas.

The bleach-works of Lancashire and Glasgow are among the largest and finest of our manufacturing establishments; exhibiting mechanical contrivance, chemical knowledge, and those powers of combination and classification so remarkably developed where many hundred persons are employed.

BLEIBERG, is the seat of one of the Austrian mining departments, and its neighbourhood contains valuable lead mines, which produce annually about 2000 tons of metal. About 80 tons of red lead also are annually produced. There are besides valuable copper mines and marble quarries in the neighbourhood.

BLIND, MECHANISM FOR THE. There are many ingenious mechanical contrivances for assisting in the instruction of the blind.

In the infancy of the art of teaching the blind, *raised music* was invented, in order that they might be enabled to acquire their lessons independent of a master. In 1827 the Society of Arts gave the large silver medal for a contrivance by Don Jaime Isern, the object of which is to enable a blind composer to transfer his thoughts to paper in the usual musical notation, without the necessity of employing an amanuensis. Embossed music, and maps and globes for teaching geography, would naturally be suggested to those persons who were engaged in teaching reading to the blind by raised figures. M. Weissembourg, a blind man of Mannheim, appears to have been the first person who made relief-maps; up to which time the instruction given to the blind on geography was merely oral. Various methods for producing maps of this character were employed, but at first without success; after a time, however, the chief difficulties were conquered, and a process which is minutely described by Dr. Guillié has supplied all the maps which have been in use at the Parisian Institution to the present time. The map of a country is pasted upon thick pasteboard, a wire is then bent round the curves of the coast, and along the courses of the rivers; these wires are fastened down, and a second map in every respect similar to the first is pasted over it; when this is pressed, the windings of the wire will be easily traced by the touch. Another plan consists in having a metal plate engraved with all the lines, elevations, boundary marks, positions of towns, &c.; from this plate impressions are struck in pasteboard, which produce a perfect embossed map. There is an elementary treatise on mathematics, by the Rev. William Taylor, of York, called 'The Diagrams of Euclid's Elements of Geometry, arranged according to Simpson's edition, in an embossed or tangible form, for the use of blind persons who wish to enter upon the study of that noble science,' York, 1828.

The intellectual education of the blind has made great advances within the last few years. The interest connected with the question of 'Types for the Blind,' to which considerable impetus was given by the Society of Arts for Scotland at Edinburgh, who offered their gold medal for the best alphabet for the blind, has tended greatly to bring about this change. The late Mr. John Alston, the treasurer of the Glasgow Asylum, adopted the plain Roman characters deprived of their small extremities —the *sans-serif* of type-founders; and, finding that it could be easily read, that it would also enable any seeing person who could read to be a teacher of the blind, he at once procured founts of type, and published several works in raised letters; the success of these for their special object established the pre-eminence of his alphabet. He also brought out some beautiful embossed music and maps; and he published the Old and New Testaments in 19 vols., super-royal 4to. The paper used for these works is strongly sized, to retain the impression. In order to account for the great extent of the Bible, it must be borne in mind that the paper can only be printed on one side, and that the letters require to be of considerable size in order to be distinct to the touch. The printing is effected by a copper-plate press. The types being strongly relieved, and liable frequently to give way under the heavy pressure required, it was necessary to have them re-cast four times during the progress of the work. The whole of the works have been completed within the walls of the Glasgow Asylum, a man and a boy acting as compositors, there being one pressman, and the ordinary teacher acting as corrector of the press.

The different kinds of industrial works executed by the blind are nearly the same in all the asylums, varying slightly with the requirements of the district: at Glasgow they are house baskets of all kinds, mill baskets and hampers, door-mats, twines, mattresses, hair-friction gloves, curled hair for upholsterers, hearth and door rugs, table rugs, fringed rugs, articles of needle-work, stockings and pansoufles, nets, sacks and sacking.

BLOCK MACHINERY. The vast number of blocks constantly required for the use of the English navy and the mercantile marine of this country may be understood from the fact, that upwards of 1400 blocks of all sorts are needed for fitting one ship of 74 guns; while for smaller vessels, although the sizes may be different, the number will not materially vary from what is here stated. These blocks are a kind of pulley, for fastening and guiding the rigging. It was long a matter of considerable moment to devise means for simplifying the mode of manufacture, which requires great accuracy, and thus diminishing the cost. In 1781 a large manufactory was established at Southampton by Mr. Taylor, who had secured a patent for an improved method of making sheaves, and who further adapted machinery for cutting the timber and shaping the shells of the blocks. Mr. Taylor for some time supplied all the blocks required for the navy; but shortly after the expiration of his patent machinery was introduced into the dock-yard at Portsmouth, and the government undertook the manufacture, with the double object of economy, and of being independent of any individual for the supply of an article of first necessity for the equipment of ships.

About this time (1801) the late Sir M. I. Brunel succeeded in completing a perfect working model for constructing both the shells and sheaves of blocks. This model being submitted to the inspection of the Lords of the Admiralty, the invention was at once adopted by government, and the inventor was engaged to superintend the construction of the requisite machinery upon a scale sufficiently large for making blocks to supply the whole naval service of the country. The completion of this machinery occupied nearly six years, and was not brought into full operation until September 1808, since which time it has been found to work without requiring any alteration. It is a truly beautiful combination of mechanism. It consists mainly of an assemblage of saws and lathes, forming an extensive series of machines all of which are set in motion by one steam-engine. By some of these the logs of elm from which the shells are to be formed are cut up into pieces of suitable dimensions; others bore the holes for the pins or axles, and cut the mortices into which the sheaves are to be placed; others cut off the corners and complete the rounding and shaping of the shell by very ingenious arrangements; and another, the scoring-machine, cuts the grooves intended to receive the rope by which the block is to be suspended. Another series of apparatus is provided for cutting the lignum-vitæ of which the sheaves are made into slices, sawing them to a circular shape and cutting a round hole in the centre, fixing in the centre hole a metal *coak*, or ring, through which the axis is to pass, forming the groove in the edge of the sheave, and turning and polishing the iron pins for the axles. It is found that with this machinery ten men can perform the work that previously required one hundred and ten, and can easily produce 140,000 blocks per annum. Sir M. I. Brunel received 20,000*l.* from government as a reward for his ingenuity; yet it is said that the *savings* of four years, as compared with the cost of blocks made in the former manner, were sufficient to defray this sum and the whole cost of erecting the buildings and machinery. So important has this mechanism been regarded, in a national point of view, that duplicate machines have been constructed in the Chatham dock-yard, to be used in case of accident to those at Portsmouth.

Ship's blocks for the mercantile navy are still made by hand, and improvements are frequently made therein.

Among many recent patents relating to ship's blocks, one by Mr. Stowe, of Bermuda, describes the use of a metal fork which contains the block, and which has a hole drilled in the lower part of each leg; through this pair of holes is passed the spindle on which the spear revolves. Another patent, taken out by Capt. Chamier in 1849, relates to improvements in the strapping, the cheeks, and the sheaves. Instead of the ordinary rope strapping, a coil of strands of iron wire is used, coated or painted for preservation; the cheeks are formed of two thin metallic sheets, one flat and one convex, filled up by soft metal between them; the sheave is formed of three metal discs—the outer ones bent, and having their ends turned over to form the groove for the rope, while the centre one is kept straight.

BLOOD is useful for many purposes in the Arts. The blood of the bullock is employed for the clarification of wines and spirits; for the preparation of adhesive cements; for mixing with coarse paint for out-door work; as an ingredient in some modes of bleaching; and as a manure. Dried or powdered blood is prepared for export to the West Indies, where it is used in clarifying sugar; the drying is effected by exposing the bullock's blood to currents of warm air. Dried bullock's blood is said to be much used in adulterating musk.

BLOW-PIPE. This instrument, in the simple form in which it has long been employed by jewellers and others in soldering upon a small scale, is a metallic tube seven or eight inches long, about a quarter of an inch in diameter at one end, and gradually tapering to a fine point, pierced by an extremely minute orifice at the other. The tube is bent to a right angle about an inch or an inch and a half from its smaller extremity; and, the larger end being inserted in the mouth of the operator, it is used to direct the flame of a lamp upon the solder or other substance to be heated. The substance thus operated upon is laid upon a piece of charcoal held in the left hand of the operator, and a steady gentle current of air is impelled through the pipe by contracting the muscles of the cheek, the mouth having been previously inflated with air. The power of thus producing a blast without the aid of the lungs, and of respiring during the operation, is an important accomplishment, as without it the health may be injured by the use of the blow-pipe; and experience is necessary to enable the operator to regulate the strength of the blast, which if too great will diminish the heat by throwing too much air into the flame, and if too weak will produce a feeble flame.

In the simplest form of blow-pipe, the collection of water from the condensed moisture of the breath prevents the continuance of the blast for any length of time. This inconvenience is avoided by making the blow-pipe in two pieces, and interposing between them a receptacle for retaining the water, and preventing its entrance to the finer portion of the pipe.

The application of the blow-pipe to scientific purposes appears to have originated about 1738, when Antony Swab, a Swedish bergrath, or counsellor of mines, employed it in the examination of ores and minerals. Cronstedt, whose system of mineralogy, based upon the chemical composition of the minerals, was published in 1758, by the employment of fluxes in the experiments performed with this instrument, may be considered the founder of a new department of chemical science; Bergman published a Latin treatise embodying the results of his researches with it in 1779; and Gahn, though he left no work on the subject, far exceeded any of his predecessors in experiments with this instrument, the results of which were subsequently given to the world by J. J. Berzelius, in a treatise, of which English, French, and German translations have appeared.

Modifications of the common blow-pipe have been contrived with jets of hydrogen or oxygen, or of the two gases combined in definite proportions. By the oxyhydrogen blow-pipe, which, though highly dangerous in the form in which it was originally contrived by Dr. Hare, of Philadelphia, early in the present century, has by successive improvements, been rendered a safe apparatus, the hardest and most refractory substances, including all kinds of jewels and other stones, metals, rock crystal, and every description of porcelain, may be fused or sublimed, and the most brilliant effects of combustion may be produced.

BLOWING MACHINES. Bellows, or machines for directing a current of air upon a fire, to excite the requisite intensity of combustion for metallurgical and other operations, are of very early origin. Rosellini represents an Egyptian painting in which a man is engaged in working two pairs of bellows with his feet, having strings to assist in raising the boards of the exhausted pair to admit a fresh supply of air. Bellows consist, essentially, of an air-tight chamber capable of alternate expansion and contraction, and furnished with two valves, one opening inwards to admit air while the chamber is expanding, and the other opening outwards into a pipe or muzzle, to allow the air to escape when the chamber is compressed. In some of the recent Expositions of Manufactures, bellows have been exhibited which show great beauty in form and ornament.

The blast from common bellows being necessarily intermittent, and variable in intensity, it is necessary, when a continuous blast is required, either to employ two or more separate bellows or pairs of bellows, working alternately; or, where more perfect equability is required, to direct the air expelled from the bellows into a second chamber of variable dimensions, which is kept under a constant and uniform pressure, and from which the blast is directed into the nozzle. In forge-bellows of this construction three boards are used, connected by leather sides, which are kept in regular folds by hoops of cane. The middle board, to the upper side of which the nozzle is attached, is fixed in a horizontal position, and the upper and lower boards are moveable, forming two chambers, of which the lower one is kept distended by weights excepting when the board is raised by a lever and chains, and forms the part analagous to ordinary bellows; while the upper one, which is constantly compressed by weights attached to the top board, constitutes the air-chamber or reservoir. In the best smith's bellows the boards are circular, instead of being pear-shaped like the domestic machine, and in some helical springs are used instead of weights. Very simple and efficient bellows may be made of wood alone, on the model of common bellows, by the use of two boxes sliding upon one another so as to constitute, jointly, a chamber of variable dimensions; and the missionary Williams, in the absence of leather for ordinary bellows, constructed an efficient blowing-machine of wood, consisting of two square boxes with pistons arranged to rise and fall alternately. Wooden bellows are sometimes used in large organs.

The *trombe*, or *trompe*, is a blowing engine often referred to by old writers, in which a shower of water, in its fall down a large vertical tube, draws with it so much air as to produce a powerful current, which is conducted from the bottom of the tube, where it is separated from the water, to the furnace. The most important blowing-machines however for metallurgical operations, are those in which the air is alternately drawn into and expelled from large cylinders resembling those of a steam-engine, by the action of pistons impelled either by water wheels or by steam-engines. The first machines of this character were constructed by Smeaton for the Carron Foundry about 1760. The cylinders, of which any number may be employed, usually force the air into large air-chests, or chambers of iron or masonry, from which it is conducted to the blast-pipes, which are called *tuyeres* or *tweers*. The force of the blast may be regulated either by a contrivance resembling a safety-valve, allowing the air to escape when the pressure exceeds a given degree, or by connecting with the air-chest an apparatus similar to a gasometer.

One of the largest blast-engines or blowing-machines ever constructed is now in use at the Coltness Iron Works in Scotland. The high pressure cylinder is 54 inches in diameter, 9 feet stroke, and weighs 10 tons; the blowing cylinder is 122 inches in diameter, 9 feet stroke, and weighs 31 tons. The beam is 36 feet long, 6 feet broad in the centre, and weighs 36 tons. The connecting rod gives 14 strokes per minute, with a stroke of 12 feet. The fly-wheel is 30 feet in diameter, and with its shaft weighs 35 tons. The steam pipes are 21 inches in diameter. The working mechanism is supported on two columns and entablature, weighing 22½ tons. The pedestals on which the machine stands are composed of 1900 tons of solid masonry. This gigantic machine was constructed to supply a blast to ten iron furnaces.

BLUE, as a pigment. The substances used for this purpose are of different natures, and derived from various sources: they are all compound bodies, some natural and others artificial.

Prussian Blue.—This beautiful pigment was discovered in 1710 by Diesbach, a manufacturer of Berlin. It is a compound of cyanogen and iron, is inodorous, tasteless, insoluble in water, alcohol, æther, and oils. It is hygrometric, attracting water strongly from the air, which it retains until heated to nearly 280°. Prussian blue is employed both as a water colour and in oil; in the latter case, on account of the deficiency of what is termed *body*, it is usually mixed with white lead, and it will bear admixture with a large portion of this on account of the intensity of its colour. Its stability is very considerable, and it is not only used as a pigment, but also as a dye.

Indigo.—This fine blue is extracted from different species of *indigofera* in the East Indies, and Guatimala in North America, of which the latter is most esteemed. [INDIGO.]

Blue Verditer.—This pigment is used as a water-colour, and chiefly in the manufacture of paper-hanging. It is a gritty powder of a very fine light blue. It is a carbonate of copper.

Ultramarine.—This splendid and permanent blue pigment was originally, and indeed until within a few years exclusively, prepared from a mineral called Azure Stone, or Lapis Lazuli; but it is now prepared by artificial means. It has hitherto, on account of its high price, been used almost exclusively by artists, both as a water-colour and in oil; but on account of the reduced charge at which it will probably be hereafter obtained, it will doubtless be rendered much more extensively useful.

Cobalt Blue.—This was proposed as a substitute for ultra-marine before the invention above described had rendered this latter colour easily obtainable at a moderate price; it is of great permanence, but is not so fine as the ultra-marine, and will hereafter be probably little employed.

Smalt is a blue colour also prepared from cobalt, but is generally used rather to diminish the yellow tint of writing paper and of linen, and to give a bluish colour to starch, than strictly speaking as a pigment; it is merely glass rendered blue by oxide of cobalt, and this, when reduced to a very fine powder, is commonly called *powder blue*.

BOAT. [LIFE-BOAT; SHIP-BUILDING.]

BOBBIN NET. [LACE.]

BOG. The name of bog has been given indiscriminately to very different kinds of substances. In all cases the expression signifies an earthy substance wanting in firmness or consistency. In some cases, where springs of water, or the drainage from an extensive area are pent up near the surface of the soil, they simply render it soft or boggy, and in this state the land is perhaps more properly called a quagmire. A second state of bog is where in addition to the condition just described, a formation of vegetable matter is induced, which, dying, and being reproduced on the surface, assumes the state of a spongy mass of sufficient consistence to bear a considerable weight. Bogs of this description are numerous and extensive in Ireland, where they are valuable, from the use made of the solid vegetable matter both as fuel and as a principal ingredient in composts for manures. Where the turf has been cut away for these purposes, several bogs have been reclaimed by draining; and the subsoil is then readily brought into cultivation. Bogs also occur in Cornwall, and other parts of Great Britain, where the form of the surface and the nature of the earth favour the general condition under which bog is formed. The bogs of Ireland are estimated in the whole to exceed in extent 2,800,000 English acres.

When bogs become consolidated or compressed, they are called peat-mosses. An extensive tract of peat-moss (Chatmoss) in the county of Lancaster has attracted public attention from the circumstance of the Liverpool and Manchester Railway having been carried through it. Chatmoss (6 miles long by 3 broad) has a depth of 30 feet of spongy moss, which Mr. Stephenson succeeded in making fit to bear a railway, by filling it with an enormous mass of solid earth. The late Mr. Roscoe brought part of Chatmoss into a state fit for cultivation by marling and manuring.

Many of the Irish bogs contain wood of a peculiar kind, called bog-oak, bog-yew, &c.; of which statuettes, models, and ornaments are carved; beautiful specimens of this kind were displayed at the 'Dublin' Exhibition of Manufactures in 1850.

The present attempts to give commercial value to the peat of Dartmoor are noticed elsewhere. [PEAT.]

BOHEMIA. The productive and industrial resources of this important country have been briefly noticed in connexion with the Empire of which it forms a part. [AUSTRIA.]

BOILER. This name is now most commonly applied to the close vessels used for the generation of steam. Such boilers, to lessen the danger of explosion, are almost invariably made of wrought metal, which, if burst, will tear rather than fly to pieces, as cast metal would do; and the plates made for the purpose are formed of the best and toughest metal, and rolled or wrought with peculiar care. Engineers differ as to the comparative merits of iron and copper as a material for steam-engine boilers. Most however admit that iron, when of good quality, has the greatest cohesive strength, although the greater uniformity of texture in sheet-copper renders it safe to construct copper boilers of less thickness than those of iron, to withstand a given pressure. Further than this, supposing an explosion to occur with a copper boiler, it is likely only to produce a rent or tear in the metal, while an iron boiler, even though wholly of wrought plates, is frequently blown to pieces.

Dr. Ritterbandt's plan of removing from steam-engine boilers the incrustations with which they become coated, is a valuable recent improvement. All the fresh water employed in boilers contains lime, in the form of a soluble bi-carbonate. The heat converts this into an insoluble carbonate, which falls to the bottom of the boiler, and carries with it any floating masses of other insoluble matter. When salt water is used the same results occur, but in addition to this, the carbonate forms nuclei for the accrescence of sulphate of magnesia, chloride of sodium, and other saline compounds, which crystallize and precipitate much sooner than would otherwise be the case. The incrustations so formed within the boiler thicken its substance, occasion a greater expenditure of fuel for the heat to reach the water, and renders the boiler liable to burst; because as the incrustation is not so good a conductor of heat as the metal, the latter becomes burnt and weakened before the heat of the furnace can penetrate through the incrustation to the water, and thus explosion may occur. Dr. Ritterbandt's method is a chemical one. He introduces into the water of the boiler some ammoniacal salt, the acid of which, mixing with the lime, will form a soluble salt instead of an insoluble carbonate of lime. It is not therefore simply a cure for a disease; it is a prevention of the disease from taking place at all, and is on that account a very scientific method. There are many ammoniacal salts to choose from, such as the muriate, the acetate, and the nitrate. The quantity of ammoniacal salt used must depend on the quantity of lime in the water.

The *Times* gave valuable testimony, in 1847, to the efficacy of Ritterbandt's process in the following paragraph;—"The invention has been tried for nearly twelve months upon the boilers of the engines printing the *Times*, working on an average seventeen hours *per diem* throughout the year. Not only have the boilers been kept perfectly free from deposit, but an incrustation which was formed previously to the application of the invention has been completely removed. We can further state, that neither the boilers nor any part of the machinery, has been in any, even the slightest degree acted upon or injured by the action of the remedy in question."

The patented improvements in steam-engine boilers, introduced within the last few years, are so varied that we cannot even enumerate them.

BOILING OF FLUIDS. When fluids are heated to such a degree as to be strongly agitated and produce much vapour, they are said to boil, or be in a state of ebullition. Under similar circumstances, the temperature at which this occurs is always the same in the same fluid, and is called its *boiling point*, being the greatest heat which the fluid is capable of acquiring. When the vapour which arises from a boiling fluid is condensed, the resulting liquid is perfectly similar to that from which its vapour was produced, having suffered no chemical change. Most metals, though rendered fluid by melting, never boil, and many oils become decomposed before reaching a temperature at which they would otherwise boil.

When water is heated, there is a point, just before it has acquired it highest temperature, at which a slight noise, or rather a succession of noises, is heard, usually called simmering. This is occasioned by the formation of minute bubbles of vapour, at the bottom of the vessel, and nearest the source of heat, which, being specifically lighter than the water in which they are formed, rise into the upper and cooler part of it, and are then condensed. Soon after this and when the whole of the water has acquired its highest temperature, the bubbles of vapour rise to the surface, and there bursting constitute steam, which, being transparent and colourless, is consequently invisible, but when it comes into contact with the cold air it undergoes partial condensation, and is then visible and appears as a mist. This temperature, under average circumstances, is about 212° Fah.; but, with variations in the density of the air, it varies as follows:—

Barometer.	Boiling point.
26 inches	204.91
26.5	205.79
27	206.67
27.5	207.55
28	208.43
28.5	209.31
29	210.19
29.5	211.07
30	212.00
30.5	212.88
31	213.76

On ascending mountains, by the consequent diminution of atmospheric pressure, and in proportion to it, water is found to boil at a lower temperature. Thus, on the summit of Mont Blanc, which is about 15,000 feet above the level of the sea, Saussure found water to boil at 178° of Fah., or 34° below its usual temperature. Fluids boil at 140° less in vacuo than under ordinary atmospheric pressure; so that water in vacuo boils at about 72°. On the other hand, if the pressure of air be increased, the boiling point becomes higher. Thus, Southern established the following relation between the barometric pressure and the boiling point of water:—

Atmospheres.	Inches of Mercury.	Temperature.
1	29.8	212°
2	59.6	250.3
3	89.4	275
4	119.2	293.4
5	149	309.2
6	178.8	322.7
7	208.6	334.4
8	238.4	343.6

It is to be observed, that the temperature of the steam is always equal to that of the water from which it is generated. The boiling point of any one liquid, as above stated, depends mainly on the pressure to which it is exposed; but it is also slightly affected by the substance of the vessel containing it, and the contiguity or immersion of other bodies.

The following are the boiling points of a few liquids under the same atmospheric pressure:—

	Boiling point.
Muriatic æther	52°
Sulphuric æther (sp. gr. 0.7365 at 48°)	113
Bisulphuret of carbon	113
Acetic æther	160
Nitric acid (sp. gr. 1.5)	210
Oil of turpentine	314
Naphtha	320
Phosphorus	554
Sulphur	570
Sulphuric acid (sp. gr. 1.848)	600
Mercury	662

BOKHA'RA, a country situated in Central Asia, exhibits the industry of its inhabitants in the cultivation of their lands. The larger and the smaller canals, both of which are numerous, must have required a good deal of labour when they were first made; and they are still kept up at a considerable expense. Cotton, hemp, sesamum, tobacco, and a few dye-stuffs are cultivated.

Gold is found among the sands of the Amoo, and collected from it in many places along its banks. All other metals are imported from Russia. Salt is dug out in masses in some parts of the desert, and on the banks of the Amoo, below Chard-jooee. Alum and brimstone are got in the neighbourhood of Samarcand, and sal-ammoniac in its native state occurs in the mountainous district.

The mechanical arts are not neglected, and some commodities are even made for exportation. The most extensive manufactures are those of cotton and silk; and some kinds of cloth, in which both materials are combined, are in great demand in Russia for morning dresses of the rich nobility. The dye of all their manufactured goods is excellent. The Bokharians do not understand the art of tanning so well as the Russians, but they make excellent Marocco leather. Their swords are good, but much inferior to those of Persia.

The chief city, also called Bokhara, is a place of much commercial importance. There are six commercial routes radiating from it. One of these leads to Samarcand, Khokand, and Kashgar; another to Khiva and Astrakhan; a third through the Kirghis region between the Sea of Aral and the Caspian; a fourth to Merve and Meshed; a fifth to the Oxus and Herat; and a sixth to Balkh, Khooloom, Bameean, and Cabul. Most of the commodities of Asia and Europe find their way along one or other of these six routes.

BOLE, an earthy mineral which occurs in amorphous masses in various countries, as in Armenia, Saxony, Tuscany, Siena, Ireland, and the Isle of Skye. The colour of Bole is various, either yellow, brown, red, or brownish, and pitch black; it is dull, has a greasy feel, and adheres to the tongue. Its fracture is conchoidal, yields to the nail, and the streak is shining. The chief varieties are the Armenian and the Lemnian bole, both of which consist mainly of silica and alumina. They are used to a small extent as pigments, and also in medicine: but not to so great an extent as formerly.

BOLETUS, an extensive genus of fungi, consisting, according to the old botanists, of leathery masses, which are sometimes of considerable thickness, and having the spores lodged in tubes which occupy the same situation as the plates in the gills (or hymenium) of the common mushroom.

The true Boleti are generally found growing on the ground in woods and meadows, especially in pine woods. Some are eatable; some are used in medicine; while one variety, when dried and sliced, furnishes the German tinder, or AMADOU.

BOLSOVER STONE. The yellow limestone of Bolsover, in Derbyshire, is used in the construction of the New Houses of Parliament, in London. It was selected for its durability, strength, fitness for ornamental work, and colour. It is a combination of carbonate of magnesia with carbonate of lime, in small granular crystals, without flinty nodules or other blemishes.

BOLTHEAD, a chemical vessel, usually of green glass, and of a globular form, with a narrow neck. It is chiefly employed in the process of sublimation.

BOLTON. This important Lancashire town has maintained an eminent position in manufactures for many centuries. Leland speaks of its being a market for cottons and coarse yarns; and another writer (Blome), who wrote somewhat later, describes it as 'a fair well-built town, with broad streets, with a market on Mondays, which is very good for clothing and provisions; and it is a place of great trade for fustians.' There seems to be little doubt that the making of woollens was introduced by some Flemish clothiers who came over in the 14th century; that other branches of trade were introduced by the French refugee manufacturers, who were attracted by the prosperity of the neighbourhood; and that the manufacture of cotton cloth was improved, and in many of its kinds originated, by some emigrant weavers, who came from the palatinate of the Rhine.

Bolton made no great advances in population until the improvements in the machinery for spinning cotton gave an impetus to the trade, which has been gradually increasing ever since. Almost the first invention of importance originated in this town. It was a machine which combined the principles of the spinning-jenny and the water-frame, and was called a *mule*, by its inventor, Samuel Crompton. This ingenious man lived at 'Hall in the Wood,' near Bolton, and had to struggle for an existence, while his invention was enriching others. 'Hall in the Wood' still exists, a memento of the rise of the cotton manufacture.

While Crompton's invention was enriching others, Sir Richard Arkwright, another native of Bolton, who had risen from a very obscure condition, had established large factories in Derbyshire, where he carried the cotton machinery to the greatest perfection. The opposition made by the labouring classes in Bolton to the improvements in machinery has, at various times, driven the most lucrative branches of employment from that town to other places. The introduction of the mule and of the power-loom was not accomplished until they had enriched other communities for some time. After a while cotton factories, filled with machinery upon the best principle, began to rise up in various parts of the town. Foundries and machine manufactories followed them, and a great extension was immediately given to the trading interests of the place.

The cotton mills of Bolton are very numerous; and some of them are among the largest in the county, employing more than 100,000 spindles each. The weavers of Bolton produce a great variety of fabrics, probably a greater variety than any other single place in the county. Plain and fancy muslins, quiltings, counterpanes, and dimities, are the chief kinds of cloth; but cambrics, ginghams, &c.,

are also woven. Formerly, fustians, jeans, thicksetts, and similar fabrics, were the principal articles made in the town; but these descriptions of cloth are now chiefly produced in the power-loom, as well as calicoes and dimities. The bleach and dye-works, especially the former, in the town and neighbourhood are among the largest in the kingdom; and there are likewise a few print-works. A great proportion of the cotton goods manufactured here are sold in Manchester, where the manufacturers have warehouses for the storing and sale of their cloths; they meet their customers there from all parts of the country, one, two, or three days of each week.

Mr. Harris, superintendent of the Bolton Police, in his Police Report for 1849, made to the Corporation, gives the following interesting details respecting the manufactures of Bolton, in the year just named; these details relate to the borough only, and do not include the other townships of the parish.

	No.	Steam Horse-power.	Hands Employed.
Cotton Mills	53	2200	9759
Foundries and Forges	22	590	3043
Bleach Works	8	628	937
Paper Mills	1	124	118
Coal Mines	5	85	64
Gas Works	1	...	43
	90	3627	13,964

Many of the above items fluctuate so much, that the table can be regarded only as a useful approximation. Several new cotton mills have since that date been built at Bolton. The attempts occasionally made to introduce the silk manufacture into Bolton have only been partially successful. The manufacture of steam-engines and machines is carried on to a large extent. The town is abundantly supplied with coal, which lies beneath and around it.

Counterpanes and other products of Bolton industry will be exhibited at the grand display of 1851; and many of the workmen in the factories have subscribed to the general fund for the Exhibition.

BOMB, the original name of what is now called a *shell*, is a hollow globe of iron, which, when charged with a certain quantity of gunpowder, is projected from a mortar or howitzer, generally at a considerable angle with the horizon, in order that, by the momentum acquired in its descent, it may crush the roofs, and, by exploding, destroy the buildings on which it may fall.

In 1688 there was cast in France an enormous bomb, which is said to have been in the shape of an egg, and to have been capable of containing 7000 or 8000 pounds of powder; it was to have been discharged against the Algerines, but it was not employed, probably in consequence of an opinion that it would not have had the intended effect; and no attempt has since been made to project such an immense mass of metal. While the citadel of Antwerp was besieged by the French army in 1832, shells twenty-four inches in diameter were thrown from the largest mortar which has been employed in modern warfare; the shell or bomb was capable of containing ninety-nine pounds of powder, and when charged weighed 1015 pounds.

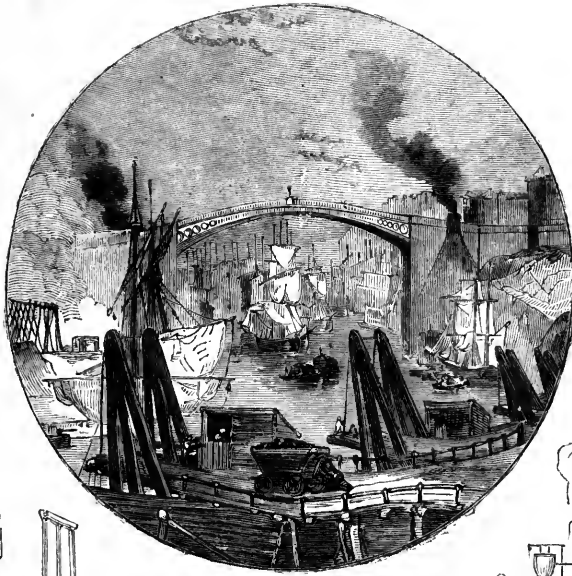
BOMB-PROOF. This name is given to a military magazine, or other building, when its roof has sufficient thickness to resist the shock of shells falling on it.

BOMB-VESSEL, a ship of about 350 tons burthen, usually forming part of a fleet intended by a bombardment to destroy or compel the surrender of some town situated on the sea-coast. It carries one 13-inch and one 10-inch mortar, besides two 6-pounder guns, one 12-pounder, and eight 24-pounder carronades. The mortars are placed on traversing platforms in the middle of the gun-deck, and they may be fired over either side of the ship at elevations never less than 45°.

BOMBAX. The wood of this genus of trees is soft and spongy, and is frequently used for making canoes. One species, the *silk-cotton tree*, is very large; the down, which is contained ln the seed vessel, is soft, but is too short to be used in the manufacture of cloth. It is made into hats and bonnets, and used for stuffing chairs and pillows by the poor people in the districts in which it grows. It is not made into beds, as it is reputed unwholesome to lie upon. The trunks of the largest are made into canoes, and some of them will carry from 15 to 20 hogsheads of sugar. The bark of another species is used in making ropes.

BOMBAY. This great and important city is more distinguished for commerce than for manufactures: for exchanging the produce of India for that of England, than for producing on its own account. Yet there must necessarily be much manufacturing carried on. The property is principally in the Parsee inhabitants, who are also the principal merchants; and it is usual for every European house of commerce to contain one or more Parsee partners, who supply a great part of the capital. The shops and warehouses belonging both to European and to native merchants and traders are upon a large scale.

The docks within the fort, although the property of the East India Company, are entirely under the management of Parsees, by whom merchant-vessels of 1000 to 1200 tons



COAL DROPS AT SUNDERLAND.

No. 11.

burden, frigates, and even line-of-battle ships are built. These docks were about forty years ago enlarged and improved under the superintendence of Major Cooper of the Engineers. The buildings are greatly admired for their architectural beauty; and the slips and basins are calculated for vessels of any size. Bombay being situated between the forests of Malabar and Gujerat, receives supplies of timber with every wind that blows. Ships built of teak-wood are much more durable than those built with European timber; they have been known to last more than 50 years. From the cheapness of labour, ships were formerly built at Bombay for three-fourths of the cost in England; but recent experience has shown that ships can be built cheaper in England. The Minden, a 74 gun ship, launched at Bombay, in 1810, was constructed entirely by Parsees, without any assistance from Europeans; and since that time several frigates and line-of-battle ships have been built at these docks.

In addition to its trade with Europe and with China, a very great traffic is carried on by coasting-vessels with all the ports on the western side of India, from Cape Comorin to the Gulf of Cutch. The vessels thus employed vary in size from 10 to near 200 tons burden, and nearly 800 of them are registered as belonging to the port. The articles which form the principal part of this trade from Bombay are European manufactures, and the produce of Bengal and China, the returns being made in cotton-wool and cloths, timber, oil, and grain from the northern ports, and from the south, cotton, hemp, coir, timber, pepper, rice, and cocoa-nuts.

The merchandise thus brought to Bombay is in great part re-exported in larger ships to different parts of Europe, to North and South America, to Canton, to the Arabian and Persian Gulfs, and to the Bay of Bengal. The goods sent from India to China comprise principally cotton wool, opium, metals, spices, dye-woods, and woollen goods. From the Arabian and Persian Gulfs, Bombay receives raw silk, copper, pearls, galls, coffee, gum-arabic, copal, myrrh, olibanum, bdellium, assafœtida, dried fruits, horses, and bullion. The returns are grain, Bengal and China sugar, British manufactured goods, cotton and woollen, and spices. The merchandise sent to Calcutta from Bombay, in return for sugar, indigo, and rice, are timber, coir, cocoa-nuts, sandal-wood, and cotton.

Cotton forms the most important article of export from Bombay. It is received from the provinces of Gujerat and the Concan, from Malabar, Cutch, and Sinde. Bombay has exported more than 100 millions of pounds of cotton in one year, besides exports to other places.

The following were the imports into and exports from Bombay during the years stated:—

Years.	Imports.	Exports.
1834 ..	£3,653,319 ..	£3,303,515
1836 ..	4,429,127 ..	5,451,554
1838 ..	4,444,693 ..	4,236,027
1840 ..	4,831,558 ..	5,018,335
1842 ..	5,542,578 ..	5,273,986

Bombay has been the chief Indian port connected with the establishment of steam communication with England. The route between Suez and Bombay is still in the hands of the East India Company; but the other portions of the great overland route are managed by the Peninsular and Oriental Steam Navigation Company; and if the present discussions concerning the Australian mails should result in the Singapore route being chosen, Bombay will have an enlarged field for its commercial enterprise.

BOMBAZINE is a woven fabric in which the warp is formed of silk, and the weft, or shoot, of worsted. The worsted is thrown on the right side, which has a twill upon it. The manufacture originated in Norwich, among the Dutch who were settled in that city, about 1575. Bombazines were formerly made of various colours, but owing to changes of fashion they are now manufactured in black only, for use as mourning.

BOMBYX. [Silk.]

BONA, is the principal rendezvous of the vessels employed in the coral fishery, which extends along the coast as far as the island of Tabarkah, which belongs to Tunis.

BONES have been of late years very extensively used as a manure, especially on poor and dry sands and gravels. When crushed and used judiciously, the advantage of bones as a manure, in distant and uncultivated spots, where the carriage of common stable or yard manure would have been too expensive, and where it could not be made for want of food for cattle, is incalculable. By means of bones large tracts of barren sands and heaths have been converted into fertile fields.

The bruising or grinding of bones has become a distinct business, and they may be bought in London and at the principal ports ready to put upon the land. They are broken into different sizes, and are accordingly called *inch bones*, *half-inch bones* and *bone-dust*. Most of the bones procured from London and the manufacturing towns have undergone the process of boiling, by which the oil and a great part of the gelatine which they contain have been extracted. The German agriculturists instead of using bone-manure on their own land, now export it to England, on account of the good price here obtainable. No less than 29,424 tons of foreign bones were imported in 1849.

Bones consist of about one-half animal matter: the rest being phosphates of lime and magnesia, and carbonate of lime. They derive their fertilising property mainly from the phosphate of lime; but in part also from the mechanical texture of the bones, and their power of absorbing and retaining moisture, which enables the plants to feed on the decomposed gelatine of the bones.

The mode of applying bone manure to the land is either by sowing from twenty to forty bushels of them per acre by the hand broadcast, as is done with corn, and harrowing them in with the seed; or by putting them into the drills by a machine made for the purpose, which is an addition to the common drilling machine.

The mill which is used to break and grind bones consists of two iron or steel cylinders, with grooves running round their circumference, the projections being cut so as to form strong teeth. These turn upon one another by means of machinery, so that the teeth of one run in the groove between the teeth of the other. The bones are put into a hopper, whence they pass between the two cylinders, where they are crushed during the passage. The bones from Germany are sometimes ground before importation, sometimes afterwards.

The uses of bones (besides as a manure) are very numerous. *Bone-ash* is prepared by calcining bones to whiteness, and reducing them to a powder; it is used for burnt hartshorn, and for making cupels. *Bone-black*, or *ivory* black, is made by a careful preparation of the *soot* of clean bones, when burned in a peculiar manner. There are successive stages in the manufacturing uses of bones; first the bones are boiled, and the grease sold to the candle and soap makers; then the larger pieces are selected for making knife-handles, &c.; then the best pieces are laid aside for bone-black; and finally the worst pieces are appropriated as manure. The coarser kind of bone-black is made into *animal charcoal*, used by sugar refiners; while the finer kind is employed in making black paint and colours, inks, dyes, &c.

Bone, as a material for knife handles and other articles, may be dyed red, black, green, purple, yellow, blue, or other colours, by the same dyes as are used for ivory. Bone is easily wrought by the saw and lathe.

BOOK-BINDING. This interesting art includes not only the fastening together of the leaves of a book; but also the preliminary operations of folding each sheet so that the several pages of which it consists may follow one another in due order, and of *gathering* or collecting together in proper sequence the several sheets, and *collating* or examining them, to see that no error has been made in the arrangement. To aid these operations certain letters or figures, called *signatures*, are placed at the bottom of the first page and one or two other pages of each sheet.

In the subsequent processes it is necessary to distinguish between the comparatively slight and loose mode of binding in cloth or paper covers, which is technically called *boarding*, and the more solid kind of binding in leather, to which, among the trade, the application of the term *binding* is limited.

If the book is to be simply boarded, the sewing of the sheets, individually, to a series of strings called *bands*, stretched in a machine called a sewing-press, is the next operation after folding and collating; but, if it is to be bound, the sheets are previously either beaten upon a smooth stone, or passed in small parcels through a rolling-press, to make them close and smooth. The bands run across the back of the book, and are often rendered invisible by cutting with a saw, in the back of the collected parcel of sheets, a series of grooves to receive them. After the sheets are thus sewn to the bands, and also connected together here and there by a *ketch-stitch*, the bands are cut so as to leave about an inch projecting beyond the book on each side, and the back is smeared over with melted glue, which further unites the back edges of the several sheets. The back is then rounded in a curious manner by a process of hammering, before the glue is fully set; and the book is compressed firmly between two boards, with the back projecting a little, while the back is further beaten so as to make it spread out a little over the edges of the boards. If for binding, the edges of the sheets are then *ploughed* or cut with a machine to a perfectly flat and smooth surface, the convexity of the back being temporarily destroyed while the front edges are cut, so that they may be cut flat, and afterwards restored, so as to draw them into a corresponding concavity. If the book is only to be boarded, it is not usual to cut the top edges, which, being folded, are pretty smooth and regular; and the front and bottom edges, if cut at all, are only pared sufficiently to remove the principal irregularities.

The *boards* or pieces of millboard (which is a kind of strong and smooth brown pasteboard, of different degrees of thickness to suit the different sizes of books), which constitute what in ordinary language are the covers of the volume, are cut a little larger than the leaves, and, when the volume is to be bound, are laid on the sides of the book, with their back edges against the projecting or overlapping edges of the glued back, and secured to the book by passing the ends of the strings or bands, which are previously scraped thin, through holes near their back edges, from the outside, and glueing them down firmly and smoothly on the inside. In boarding, however, it is the more usual practice to paste the boards to the paper or cloth cover, leaving a space between their back edges sufficient for the back of the book, and to connect the boards with the book simply by pasting down to them the *end-papers*, or blank leaves which are applied in sewing at the beginning and end of the book. In binding, on the contrary, the leather is put on after the boards are attached to the book in the manner above described. Books are often so boarded or bound as to leave the back of the cover detached from the glued back of the book itself, which is done by interposing a double layer of paper or cloth between the back and the cover, glueing one layer to the cloth or leather cover, and the other to the back, and connecting the two layers with one another at their edges only.

Half-binding is that style of binding in which only the back and corners are covered with leather, and the sides with paper or cloth.

In the *finishing* or ornamenting of a bound book much taste may be displayed. The cut edges of the leaves are usually either sprinkled with colour, smeared over uniformly with a sponge dipped in colour, marbled, or gilt with leaf-gold; the edges being, for the last-mentioned process, previously coloured with red chalk and water, and then moistened with white of egg mixed with water, and subsequently burnished with a smooth hard stone, which polishes, but does not disturb the gold. The covers are sometimes coloured or sprinkled by the binder, and are impressed, both at the sides and back, with ornamental devices and inscriptions, by the application of heated stamps or dies, either with or without leaf-gold; such impressed devices as are not gilt being distinguished by the name of *blind-tooling*. When gold is used, the surface of the leather is prepared to receive it by the successive application of parchment-size, white of egg, and a little oil. In ordinary hand-work the patterns are produced by the separate application of a number of small dies, and engraved rollers for lines and long narrow patterns; but sometimes a number of dies are fitted together, and applied simultaneously by means of a press. This process is called *blocking*.

Much ingenuity and taste have been devoted of late years to the perfection of cloth-binding or boarding. By peculiarities in the mode of weaving the cotton cloth used for the purpose, and of subsequently stamping or embossing it between steel rollers, the textile appearance is destroyed, and a surface is sometimes produced very nearly resembling morocco leather.

The peculiarity of *india-rubber binding* (which has been imitated with an artificial cement) consists in the entire absence of sewing. The back as well as the other edges are ploughed, so as to reduce the book to a collection of single leaves, to the back edges of which a layer of caoutchouc or cement is applied. This mode of binding is well adapted for maps, music, ledgers, and manuscript books generally, as it allows the book to lie open with equal facility at any place, and the inner margin to be used, if needful, close to the edge of the paper.

Mr. Richards, a bookbinder, patented a few years ago a method of stitching the sheets by machinery; but we are not aware that it has come much into practice.

The book-binding trade has gradually assumed many of the features of the factory system. Some of the principal London firms, such as that of Messrs. Westley, have immense buildings planned expressly for that species of combination and subdivision which mark the larger departments of manufactures. Tier after tier of stories, each lighted from end to end with numerous windows; each story or range under the supervision of one foreman, and devoted to one department of binding; separate warehouses for the mill-board, the leather, and the cloth; powerful machines for embossing cloth and stamping leather; a department where females are employed in folding, collating, and sewing; another department where men are engaged in glueing, pasting, cutting, hammering, and pressing the 'boarded' books; another department for the 'roan' or 'sheep' binding; a fourth entirely devoted to those school books which (whatever be their merit), have a sale so enormous and continuous that the process of binding them is always going on; a fifth occupied by the 'extra' workmen employed in the costlier kinds of binding—such are the features of the establishments in question: establishments where many hundreds of workpeople are employed under one roof.

We may reasonably hope that our bookbinders, as well as those of foreign countries, will not be slow to contribute to the grand Industrial Congress of 1851. It is profitable, too, to glance once now and then at the curious specimens of bookbinding belonging to the 15th, 16th, and 17th centuries: many beautiful examples of such work were placed in the Mediæval Exhibition of 1850.

BOOK TRADE. The publisher of the 'Cyclopædia of Industry' has made various computations, from time to time, of the produce of the Press in this country. The data for such estimates must necessarily be inexact, and the results can only be considered as approximations to truth. They are, however, abundantly sufficient to show the prodigious increase of readers.

We may exhibit the rapid growth of the publication of *new* books, by examining the catalogues of the latter part of the eighteenth century, passing over the earlier years of the reign of George III. In the 'Modern Catalogue of Books,' from 1792 to the end of 1802, eleven years, we find that 4,096 *new* works were published, exclusive of reprints not altered in price, and also exclusive of pamphlets: we have thus an average of 372 new books per year.

The number of new publications issued from 1800 to 1827, including reprints altered in size and price, but excluding pamphlets, was, according to the London catalogue, 19,860, showing an average of 735 new books per year, being an increase of 363 per year over the last eleven years of the previous century. The demand for new books, even at the very high cost of those days, was principally maintained by Reading Societies and Circulating Libraries. When these new modes of diffusing knowledge were first established, it was predicted that they would destroy the trade of publishing. But the Reading Societies and the Circulating Libraries, by enabling many to read new books at a small expense, created a much larger market than the desires of individual purchasers for ephemeral works could have formed; and a very large class of books were expressly produced for this market.

But a much larger class of book-buyers had sprung up, principally out of the middle ranks. For these a new species of literature had to be produced,—that of books conveying sterling information in a popular form, and published at a very cheap rate. In the year 1827 'Constable's Miscellany' led the way in this novel attempt; the Society for the Diffusion of Useful Knowledge commenced its operations; and several publishers of eminence soon directed their capital into the same channels. Subsequently editions of our great writers have been multiplied at very reasonable prices. This circumstance will explain how the number of works published of late years does not exhibit a proportionate increase in the number of volumes. One compact volume may now contain as much matter as three octavos of the beginning of the century.

The 'London Catalogue of Books published in Great Britain' from 1814 to 1846—a period of thirty-three years—contains about 36,500 titles of works, shewing an average of 1106 new books per year, being an increase of 371 over the number in the former catalogue.

The Catalogue of New Books for 1849, arranged from 'Bent's Literary Advertiser,' exhibits the titles of above 2000 works—an enormous number for the issue of one year, and that not particularly favourable to publishing enterprise. In looking over this catalogue we cannot help remarking that the range of *price* is perhaps more extreme than at any former period, from the Shilling Railway Volume to the Five Guinea Illustrated Book. Luxurious and expensive books, for a few purchasers, are not less frequent than in times when dear books formed the greater portion of the Book Trade. Taking the cheap and the dear we find that a single copy of each of these 2000 books would amount to about 1000*l.*

But the most remarkable characteristic of the Press of this country is its Periodical Literature. The number of *weekly periodical works* (not newspapers) issued in London on Saturday December 21, 1850, was 87; in this number we include the 'Athenæum,' 'Builder,' 'Chambers' Journal' and 'Papers,' 'Church of England Magazine,' 'Eliza Cook's Journal,' 'Dickens's Household Words,' 'Expositor,' 'Family Herald,' 'Hogg's Instructor,' 'Home Circle,' 'Knight's Half-Hours,' 'London' and 'Industry,' 'Lady's Companion,' 'Lamp,' 'Lancet,' 'London Journal,' 'London Labour,' 'Mechanics' Magazine,' 'Punch,' 'Working Man's Friend,' &c.; the total issue of the 87 is fully 400,000 weekly, or upwards of 20,000,000 yearly.

Of these 87 weekly publications the prices vary, being 1*d.*, 1½*d.*, 2*d.*, 3*d.*, 4*d.*, 7*d.*; the total retail value of their sale, independent of the supply of them in monthly parts, we assume, upon the authority of an experienced bookseller, to be 2,500*l.* per week or 130,000*l.* per annum. Other authorities would set the number higher. A minute analysis of these Weekly Periodicals is, to some extent, satisfactory; for it shows that of the low publications—including those which may be called 'Guides to Newgate,'—the number sold is about an eighth of the innoxious publications.

The issue of *monthly* periodical publications from London is unequalled by any similar commercial operation in Europe. 287 monthly periodical works were sent out of London on the last day of December, 1850, to all parts of the United Kingdom, the bulk of them departing from Paternoster-row; to which must also be added 41 periodical works published quarterly, making a total of 328.

A wholesale bookseller, who has been thirty years an attentive observer of the progress of periodical literature, and has been nearly all that time in the midst of it in Paternoster-row, has made a variety of computations of the work of the great literary hive of industry in London on 'Magazine-day;' the results of his examinations are as follow:—

The total of the new numbers of the monthly and quarterly periodical works sold in London on December 31, 1850, was about 600,000. The total retail price of these works was 38,000*l.*

Three thousand five hundred parcels were despatched into the country by the various wholesale agents in London on this day. The total returns of these monthly and quarterly periodical works must exceed annually 1,000,000*l.*, the selling prices varying from ½d. to 7*s.* 6*d.* It must be observed that the sale on 'Magazine-day' does not by any means represent the total sale.

In addition to the monthly periodical works issued through the regular booksellers—'the Trade'—an amount quite unequalled at any former period is circulated throughout the country by a class of persons known as 'canvassers.' We are induced to think that the annual returns of such works cannot be less than 150,000*l.*

The number of *newspapers* published in the United Kingdom in 1849 was 603. They consumed nearly 79 millions of stamps at one penny, besides halfpenny stamps for supplements. At fivepence each their annual returns would be nearly 1,500,000*l.*

We recapitulate the estimated annual returns of the commerce of the press:—

1. New books and reprints—one set 1,000*l.* .. .. .. Estimated average number sold of each work 750		£750,000
2. Weekly periodicals ..	£130,000	
Monthly periodicals	1,000,000	
Canvassers' numbers	150,000	
		1,280,000
3. Newspapers		1,500,000
		£3,530,000

The English books exported in 1849 were returned as entitled to drawback of duty on 12,000 cwts.—in value 190,000*l.*

The foreign books imported in 1849 paid a duty of 7,751*l.*

The writer of this article considers that the *paper duty* enters into the selling price of books, &c., in the following proportions:—

1. New books—4 per cent. ..	£30,000
2. Periodicals—8 per cent. ..	102,400
3. Newspapers	56,250
Estimated total of duty on printing paper	£188,650

BOOT AND SHOE MANUFACTURE. Scarcely any handicraft employment engages the attention of so many persons in this country as boot and shoe making. From the artist of aristocratic circles to the cobbler who rolls himself up in a stall under a pot-house, is a wide interval; and this interval is filled up by numerous grades. At Northampton boots and shoes are made on a very large scale for the London market; they include chiefly the cheap varieties; but at some of the recent Exhibitions of Manufactures the Northampton boot-makers have exhibited specimens of workmanship which are considered to fall in no way behind those of London or Paris. At Edenbridge in Kent, and at other places, the strong coarse 'hob-nailed' shoes are made, which are so much worn by waggoners and others. The London makers import from Paris very large quantities of boot *fronts*, which when combined with other parts of English manufacture, constitute many of the 'French boots' which now glitter in the windows.

Of the circumstances of the trade, so far as regard the relations between masters and workmen, the most ample and interesting, perhaps, are those prepared a few months ago by Mr. H. Mayhew, for the 'Morning Chronicle.' The London work, and the more wretched features of it, are at any rate here depicted with much vividness.

The mechanical details of the manufacture have been well described by Mr. Devlin; who, in his 'Shoemaker,' forming one of the 'Guides to Trade,' has contrived to throw a general interest into that which would otherwise be merely technical.

Of the improvements or suggested improvements recently introduced into the manufacture, our patent records contain many examples. One inventor has suggested that the different parts of a boot or shoe should be sewn together with wire-thread instead of hempen thread. Another has proposed the use of revolving circular heels, which may be turned round in order that every part may receive equal wear. A third proposes heels to be made of an iron rim, with the vacuity filled up with gutta percha. A fourth has directed his attention to a mode of introducing a layer of gutta percha between the outer and inner soles. A fifth has introduced elastic pieces into the side of the boot to ensure a close fit round the instep. A sixth has invented a simple apparatus to assist in 'blocking' the fronts of boots. With respect to making boots and shoes by machinery, Sir M. I. Brunel invented a comprehensive plan, to be adopted for soldiers' shoes in the time of the war; but it has not acquired a permanent utility.

It has often seemed strange to persons not engaged in those trades, that boot and shoe makers should adopt such a cramped attitude as those to which we see them accustomed. In most cases of this kind there is a good reason for the adoption of that which has become very general. But be this as it may, a contrivance was introduced a few years ago, with a view to enabling a shoe-maker to ply his avocation either sitting or standing, without necessitating the stooping position which appears to be (and perhaps is) so painful. Mr. Warne, practically engaged in the craft, registered the contrivance in question. It consists of a kind of high stool, something like a desk stool, covered with a hard leather cushion. Another round cushion is placed upon the lower. There is a hole through both cushions, through which a strap passes down to an axle, wheel, and ratchet beneath. A last being placed upon the upper cushion, can be instantly bound tightly by the strap; while the last and the upper cushion can easily be moved round horizontally. A hinged seat is attached to the frame. The inventor states that every operation of boot and shoe making can derive aid from this contrivance.

Notwithstanding the large number of persons employed in these avocations in England, and the abundant supply of leather, there is still a considerable import of boots and shoes from abroad, chiefly France. In 1849 these imports amounted to 160,000 pairs of boots and shoes, and no less than 540,000 pairs of boot-fronts. The clue to this difference is, that boot fronts pay a much smaller import duty than boots and shoes.

We may expect to see a rich supply of these commodities at the forthcoming Exhibition. The boots of All Nations are worthy of comparison one with another.

BORACIC ACID, formerly called *Homberg's sedative salt* and *sedative salt of borax*, is a compound of the elementary body *boron* and oxygen. It exists not only in the form of boracic acid, but also in large quantity in the East Indies, in combination with soda, forming *borax*, or the borate of soda. Boracic acid is usually obtained from borax. It has the form of small, scaly, brilliant, colourless crystals, which have a greasy feel. This acid is inodorous; its taste is not strong, and scarcely at all acid. Dr. Bowring ('Report on the Statistics of Tuscany') describes a remarkable boracic acid lagoon, or system of lagoons, in Tuscany. They are spread over a surface of 30 square miles, and send out dense and stinking odours. The peasants long deemed the district an entrance to the infernal regions, and regarded it with great superstition. The lagoons are now the property of an enterprising manufacturer, who derives a considerable revenue from the boracic acid which he obtains from them.

Borax, or borate of soda, consists of boracic acid and soda. A crude kind of borax, imported from the East Indies, is called *tincal;* which is found crystallised on the edges and shallows of a brackish lake. Tincal is in the form of bluish or greenish white crystals, which are dissolved and recrystallised to form borax. Borax has an alkaline and sweetish taste, and effervesces slowly in the air.

Boracic Acid and Borax are largely employed as a flux for metals, as an aid in soldering, as an ingredient in cosmetics, and as a medicine. No less than 30,000 cwts., (chiefly boracic acid) were imported in 1848.

BORA'SSUS, a kind of palm-tree, which grows all over India both on the continent and in the islands, where it is esteemed of the greatest use on account of the vinous sap and the sugar which are extracted from it. The mode of obtaining the sap of this palm is by crushing the young inflorescence, and amputating the upper half; the lower half is then tied to a leaf-stalk, and has a vessel, usually of bamboo, attached to its end. The vessel gradually fills with sap, and is removed every morning; when replaced, a fresh slice is cut from the wounded end of the inflorescence,—an operation which is repeated daily until the whole of the raceme is sliced away. In procuring the sugar, exactly the same process is followed: but the inside of the receiver is powdered with lime, which prevents fermentation taking place: the juice is afterwards boiled down and finally dried by exposure to smoke in little baskets.

BORDEAUX. This celebrated city, one of the most important in France, has great facilities both for foreign and internal commerce. Wine, brandy, and fruits are the chief articles of export. The Médoc or claret wines are sent chiefly to England; the inferior sorts to Holland and Germany. England was among the best customers for Médoc wines as far back as the time of our Norman kings. The produce of this famous district of the Gironde is about 165,000 hogsheads annually. One half of the total produce of the three best vineyards, viz. Chateau Margaux, Chateau Lafitte, and Chateau Latour, comes to England. Large quantities of wine are also shipped to America; but this trade is chiefly in the hands of European and American Spaniards who are settled at Bordeaux. Other articles of commerce are, all kinds of bread-stuffs, hemp, flax, pitch and tar, cork, oil, salt provisions, hardware, metals, cotton yarn, ship timber, and rigging. Ships are fitted out at Bordeaux for the whale and cod fisheries. The manufactures of the town are jewellery and plated goods, linen, muslin, woollen stuffs, calicoes, hosiery, gloves, corks, soap, chemical products, musical instruments, &c. The town also has several distilleries, sugar-refineries, breweries, gas-works, glass and china works, tobacco-factories, rope-walks and dockyards. Colonial products, cotton, dye-stuffs, pepper, hides, tobacco, and rice, are the principal imports. There is a regular service of packets from Bordeaux to the Havanna and the coast of Mexico. The custom duties paid at Bordeaux amount to the large sum of 12,000,000 francs a year,—nearly half a million sterling.

BORING. Whether the vertical cavity for an Artesian Well is made, or the cavity of a cannon formed, or the cavity of a cylinder or barrel perfected, or a hole simply made in wood—the term *boring* is equally applied to all these operations.

Cannon are usually cast solid, and bored by machinery; and in an accommodated sense the term is applied to the similar operations by which musket-barrels, the cylinders of steam-engines, and other articles which are originally made hollow, have their inner surfaces turned to a perfectly smooth surface and cylindrical shape. The boring instruments of the carpenter consist of *awls*, which are put into soft wood, with a rotatory motion, without removing or bringing away its substance; *gimlets* and *augers*, which are supplied with cutting edges, and are partially hollowed, to allow of the escape from the hole of the detached particles of wood; and *bits* of various kinds, which also remove the wood, and are applied with greater power and precision by means of a crank-shaped instrument called a *brace*. Small holes in metals are usually bored with *drills*, which are formed with scraping rather than cutting edges, and are used either in a brace, a drill-stock capable of imparting an alternating rotatory motion by means of a bow worked by hand, or some other contrivance, or in a lathe. Boring machines of the lathe character are too various and complex to be described here. Suffice it to say, that the perfection to which they have been brought has rendered most essential service to science and manufactures, and removed one of the greatest difficulties experienced by early improvers of the steam-engine.

Of the various boring operations of the miner, that of boring Artesian wells is unquestionably the most interesting. It is performed with various kinds of chisels or *jumpers*, augers, and instruments suitable for extracting the detached fragments, attached to the lower end of an iron rod formed of many lengths screwed into one another; these instruments are either turned round, or jumped up and down, or worked with a combination of these two motions by suitable mechanism, the kind of tool employed, and the mode of working, being varied from time to time as the several strata are met with. By such means the interesting works noticed in ARTESIAN WELLS were completed.

Beart's boring tools, patented in 1844, are intended to be used in circumstances where the hole made by the borer can be kept constantly full of water. The borer itself is attached to a hollow tube instead of a solid rod, and acts as one leg of a syphon; the other leg being an excavated channel prepared for the purpose, and kept full of water. The arrangement of the several parts is such, that as fast as the fragments of rock or soil are loosened by the borer, they are drawn up with the water by which they become saturated, through the tube which forms the stem or vertical rod of the borer: this, at least, is the theory on which the inventor has founded his patent.

At the meeting of the British Association in 1846, Mr. Vignolles communicated an account of a method of boring Artesian wells, invented by M. Fauvel of Perpignan. M. Fauvel had observed that in several cases of success in boring for water with solid iron rods, so soon as the spring was tapped all the triturated particles were brought up without the use of the auger. He inferred that if the boring could be effected by a hollow tube about two inches less in diameter than the width of the auger, communicating with an injecting force-pump by a flexible tube from the surface, a result would follow similar to that which resulted from the natural power of the rising column of water. Having tested the hypothesis, he found that the well could be bored in much less time than by the former method. The plan has since been largely adopted, in some cases to very great depths.

An attempt was made by Mr. Gard, of Calstock, in 1848, to produce an improved boring machine, to effect in another way the objects intended by Mr. Beart in England, and M. Fauvel in France. His boring machine consists of a hollow cylinder to the bottom of which the boring-bit is attached in a peculiar way; and as the rock or earth is bored, the fragments force themselves up into the cylinder, where they are retained by a valve. The cylinder does not reach to the top of the bore, but requires to be raised when full, in order that it may be emptied; it however will contain so large a quantity, that the necessity of raising it will occur much less frequently than under the usual system. Instead of joining successive lengths of rod to the boring tool, the latter is raised and lowered by a chain.

At a meeting of the Cornwall Polytechnic Society, a few years ago, Mr. Prideaux proposed the adoption of a chemical means of facilitating the process of boring. He found that a stream of hydro-oxygen gas applied to a piece of granite stone produced heat; and that on the application of cold water the stone became soft, and yielded to the tool. Oxygen might be superseded by common air from a pair of double bellows; and common coal-gas might be used instead of hydrogen.

A very instructive illustration of the apparatus employed in well-boring may be studied at the Museum of Economic Geology.

BORNEO is likely, at some future time, to become an important commercial emporium. When the Dutch made an exploratory Expedition into the island in 1823, they found it rich in many materials of manufactures; and since Sir James Brooke has acquired power in those regions, the natural riches have become still further known. Diamonds, gold, antimony, tin, iron, copper, lead, and coal, are all known to exist in Borneo or its neighbouring island Labuan; and the vegetable produce is also rich and varied. If the time should arrive (and we may hope it is not far distant) when Australia will be placed in steam communication with India and China, Borneo will be in the route, and the commmercial advantages of the island will become developed.

BORON is an elementary body, and one of the constituents of boracic acid, oxygen being the other. This substance was first obtained by Davy in 1807. It is always procured either from boracic acid or from one of its salts.

Boron is a powder of a deep brown colour with a shade of green. It is devoid of smell and taste. It is not altered by exposure to the air or to oxygen gas at the usual temperatures; but when heated to about 600° it absorbs oxygen, and burning with considerable brilliancy it is converted into boracic acid. It combines with most of the elementary bodies and forms compounds which are noticed under the names of those bodies.

Minerals containing boron or any of its compounds as an essential component part are comparatively few in number, and only found in a few spots. They comprise sassoline, or native boracic acid; borax, or borate of soda; boracite, or borate of magnesia; datholite, or borate and silicate of lime; botryolite; axinite; and tourmaline. The presence of boron in any mineral may be readily detected with the blow-pipe, owing to the beautiful green tint communicated to the flame by the boracic acid.

BOSNIA, one of the provinces of Turkey, has a fair amount of natural produce, if the industry of the inhabitants would do it and themselves justice. Gold, silver, iron, quicksilver, lead, and coal, are known to exist in many districts: some of the mines are indeed rich, but are poorly worked. Among the articles manufactured are leather, coarse woollens, worsted coverlets, cannon balls, saltpetre, gunpowder, iron ware, and weapons; but the extent of the manufactures is very limited.

The exports comprise wool, honey, wax, goats' hair, hides, morocco and other leather, timber and other articles of wood, worsted coverlids, &c., horses, horned cattle, sheep, goats, swine, poultry, dried fish, pitch, and other domestic produce: and the imports consist of linens, woollens, silks, cotton goods, glass-ware, flax, steel-ware, tin, lead, copper, and iron-wares, indigo, colonial produce, &c.

BOSTON is the chief port of Lincolnshire, and a place of considerable trade. The foreign trade is chiefly with the Baltic, whence are imported hemp, iron, timber, tar, and other commodities. The chief exports consist of corn, particularly oats, large cargoes of which are sent to London. The gross receipts of customs in 1847 amounted to 40,555*l.* The vessels registered at the port in 1849 were 159: and the ships which entered and cleared the port amounted in number, in that year, to 1,833. The manufactures carried on within and around the town consist chiefly of ships, sails, canvas, sacking, iron and brass work, cooperage, ropes and cordage, leather, hats, bricks, whiting; there are also breweries and malt-houses.

BOSTON, in the United States, is one of the most important commercial cities in the republic. Several large steam-vessels form a regular line of communication between Boston and Great Britain, stopping at Halifax, and performing their voyages in 11 to 13 days; they start once a fortnight from Liverpool. Other lines of steam-packets communicate with every port of importance in the United States. The foreign commerce is very large, amounting to six or seven millions sterling annually, and employing a vast number of fine vessels. The manufactures, too, are important; but Boston is a trading rather than a manufacturing city.

BOTANY. It scarcely needs to be observed that, though botany as a science cannot be treated in this work, a knowledge of it is most important to the arts and manufactures: every increase in our knowledge of the principles which govern the vegetable kingdom, increases our store of materials for industrial pursuits.

BOTHNIA. This frigid region of Sweden and Russia cannot be expected to yield many materials of industry. Rye is the principal grain cultivated, and potatoes are largely grown. Butter and hides, which are the principal articles of export, are sent to Stockholm. The Laplanders have considerable herds of reindeer, and live upon their flesh and other produce. Fish is very abundant. The forests yield abundance of timber, including birch, pine, fir, alder, and aspen. Some of the trees yield tar and pitch.

BÖTTICHER WARE. All the collectors of old china are glad to obtain specimens of Bötticher ware. Bötticher was a chemist and druggist in Saxony, who after failing in various attempts at alchemy, tried the much more rational art of pottery. He produced, in 1703, a kind of red-stone ware; and in 1709 he succeeded in making a beautiful white porcelain—the first European example of that which had before been limited to China. He found that the proper materials were procurable in Saxony; and he established the famous manufactory at Meissena, which has since produced the well-known Dresden china.

The Bötticher ware which finds a place in our cabinets of rarities, and of which many specimens were to be seen at the Mediæval Exhibition of 1850, is generally a kind of brown or reddish brown pottery, polished in a lathe, and covered with a black or iron varnish, enriched with painting and gilding, but not fixed by fire.

BOTTLES, GLASS. The curious mode of making glass bottles is briefly described in a later article [GLASS]. We will here merely state that the making of bottles is one of the most extensive departments of the glass manufacture in this country. Besides the immense quantity used for home purposes, no less than 233,108 cwts. of glass bottles were exported in 1849.

BOTTOMRY, as a contract in commercial transactions, is a pledge of the ship as a security of the repayment of money advanced to an owner for the purpose of enabling him to carry on the voyage. This contract is usually in the form of a bond, called a Bottomry Bond, and the condition is that, if the ship be lost on the voyage, the lender loses the whole of his money; but, if the ship and tackle reach the destined port, they become immediately liable, as well as the person of the borrower, for the money lent, and also the premium or interest agreed to be paid upon the loan.

BOUCHES-DU-RHONE. This department of France is chiefly deserving of a word of mention here on account of its wine produce. Nearly 100,000 acres are devoted to vineyards. In 1846 the quantity of wine produced in the department amounted to 13,750,000 gallons, about one-half of which was used for home consumption, and the remainder exported or converted into brandy. The white wines of Cassis and Ciotat, the red wines of Séon and St. Louis, and those of Château-Regnard and Saintes-Maries are the most esteemed sorts. The number of Mulberry-trees for the production of silk exceeds a million. The olive is extensively cultivated, and the oils of this department are the best in France. The manufacturing industry of the department, too, is great. The most important products are brandy, soap, vinegar, soda, chemical products, broad-cloth, leather, hats, and perfumes. There are several sugar refineries, glass-works, tile and brick-fields, silk, cotton, and tobacco factories, and important salt-works along the coast and on the several lagunes. The commerce of the department is very active with all the southern departments, with the Levant, the coasts of Africa and Spain, and the West Indies. The exports consist of the industrial products named, and dried fruits, cork, and colonial produce. Mines of coal, marble, slate, plaster of Paris, chalk, alabaster, and potters' clay, are successfully worked. Iron and lead-mines have been discovered, but they are not worked. The chief commercial town is noticed elsewhere. [MARSEILLE.]

BOULOGNE, in a commercial point of view, is gradually becoming an important place. The connection by railway of Boulogne with Paris, and of Folkestone with London, has given rise to a large passenger-transit through Boulogne; and goods-traffic is now beginning to follow the same route. The trade of the town is considerable. The herring and mackerel fisheries call into employment a considerable capital, and several vessels are fitted out for the Newfoundland cod fishery. Coarse woollens, sailcloths, pottery, nets, and tulles, are manufactured. There are also a linen-yarn factory which contains 3,000 spindles, glass-bottle works, rope-walks, gin distilleries, sugar refineries, tan-yards, tile and brick works.

BOULTON, MATTHEW, has left a name which will live in all records of mechanical art. He was born in 1728, at Birmingham, where his father carried on the business of a hardwareman. He received an ordinary education, and also acquired a knowledge of drawing and mathematics. The death of his father left him in possession of considerable property; and, in order to extend his commercial operations, he purchased, about 1762, a lease of Soho, near Handsworth, two miles from Birmingham. In 1769 Mr. Boulton having entered into communication with Watt, who had obtained a patent for some improvements in the steam-engine, Watt was induced to settle at Soho; and on his entering into partnership with Mr. Boulton, the Soho works soon became famous for their excellent engines. The manufacture of plated wares, of works in bronze and *or molu*, such as vases, candelabra, and other ornamental articles, was successively introduced at Soho. Artists and men of taste were warmly encouraged, and their talents called forth by Mr. Boulton's liberal spirit. Boulton expended about 47,000*l.* in the course of experiments on the steam-engine, before Watt perfected the construction and occasioned any return of profit. Mr. Boulton died in 1809.

BOURGEOIS, SIR FRANCIS, is noticeable here as the bequeather of the Bourgeois collection to the custody of Dulwich college, for the use of the public. The collection was formed by Noel Desenfans, an eminent picture-dealer, who left it to Sir Francis. He at his death, left it to the widow of his friend, with the greater part of his property, for life; bequeathing 2,000*l.* to Dulwich college for the purpose of building a gallery for the pictures, the reversion of which they were to have. The Dulwich Gallery, as it is generally termed, comprises upwards of 300 pictures.

BOW, an instrument used in producing the sounds from violins, &c. It consists of a stick of Brazil wood, 80 or 100 horse hairs, and a nut to tighten these hairs in the bow. The violin bow was very short in Corelli's time, but gradually increased in length, till Viotti fixed it at 28 inches. The violincello bow is larger and stronger. That for the double-bass is short and strong, and the stick is bent, forming something like the segment of a circle, of which the hairs when stretched are the chord.

BOWS. The common bow and arrow have been known as weapons of offence in almost every country. Among the ancients the bows were made from reeds, the spath of the palm, and various kinds of elastic and tough wood; while the arrows, made of reeds or light wood, were often pointed at the ends with sharp stone instead of iron. At the present day the bow and arrow-makers have an extensive choice of materials, as well for the bow and the arrow as for the string. The cross-bow has been noticed elsewhere. [ARBALEST.]

BOX-WOOD. This remarkably close-grained wood is the produce of the *Buxus* genus of trees. The *Buxus Sempervirens* is the species which yields this valuable wood. It is a small tree common to the south of Europe; but in England it is only found on warm chalky hills, such as Boxhill in Surrey. England is supplied with box-wood chiefly from Turkey; while France receives her supply mainly from Spain. In 1815 there were box-trees cut down on Boxhill which produced 10,000*l.* For the turner, the mathematical instrument-maker, the carver, and especially for the uses of the wood-engraver, box-wood is extremely valuable. The French employ it for making coat-buttons.

At the Mediæval Exhibition of 1850 opportunity was afforded for witnessing the exquisite skill of some of the old carvers in box-wood.

BRABANT. The chief features which render Brabant interesting, in an industrial point of view, are briefly noticed under BELGIUM; BRUSSELS; NETHERLANDS.

BRADFORD. It is curious that both of the well-known towns of Bradford owe their importance to the woollen manufacture. Bradford in Wiltshire has for many centuries been noted for its fine broad-cloths, which have at all times formed its principal manufacture. 'The toune of Bradford stondith by clooth making,' Leland said three centuries ago; and this is still true.

Bradford, in the West Riding, is however the greater town of the two; for its recent progress in wealth and importance has been astonishingly rapid. The chief manufacture of Bradford and the neighbourhood is of worsted stuffs. The spinning of worsted yarn employs many thousands of workpeople, in some of the largest mills of Yorkshire, and the stuffs are woven from the yarn. Woollen yarn for the manufacture of cloths, broad and narrow, is also spun and woven at Bradford in considerable quantities; but the worsted manufacture is the staple employment of the place, Leeds and its dependencies being the more immediate seat of the woollen manufacture. The piece hall, which is the mart for stuff goods, is 144 feet long by 36 feet broad, and has a lower and an upper chamber. The business which is transacted in the piece hall at the Thursday's market is very great, and forms one of the most animated commercial scenes in the kingdom. Many proprietors of worsted mills supply the small manufacturers with yarn, besides employing a great number of looms themselves. Machinery, worked by steam, has almost superseded manual labour in the stuff manufacture, the weaving being now generally done by power-looms. The stuffs manufactured in Bradford are chiefly dyed in Leeds, the proprietors of the dye-houses being among the largest purchasers in the Bradford market. It is however understood that at the present time (1851) Bradford is rapidly rising at the expense of Leeds. Many of the woollen and wool merchants have lately left Leeds, and opened warehouses in Bradford. Several of the large firms of Manchester and Huddersfield have also recently opened warehouses in this flourishing town. Several new worsted mills have been erected between 1846 and 1850, and others are now in course of erection. The central situation of Bradford, with reference to the other clothing towns, has probably been a chief cause of this recent advancement.

The iron trade has long flourished in the neighbourhood of Bradford; indeed it is supposed that the Romans worked iron mines near this spot. There is an abundant supply of iron-ore and coal, both of excellent quality; and the well-known ironworks at Bowling and Low Moor are only a short distance from Bradford. At these foundries some of the most ponderous works in cast-iron are executed. Vast numbers of workmen are employed in different departments of the establishments—from the raising of the ore and coal, to the various marketable states of the metal. These ironworks have the reputation of being carried on with great skill; the improvements of modern times having been successfully introduced in the different branches of the manufacture.

The principal merchants and manufacturers in the trades of Bradford are wool-staplers, wool-combers, worsted-spinnners and manufacturers, worsted-stuff manufacturers, and woollen-cloth manufacturers. Several of the trades which are carried on are dependent upon the woollen and worsted trade; among them are the manufactures for combs, shuttles, and machinery.

Bradford is preparing with much vigour to take part in the Industrial Exhibition of 1851. The manufacturers require 2,000 square feet of space for their appropriation; and they have appointed a committee by whom the articles to be exhibited are grouped in five classes: viz., worsted stuffs, cotton stuffs, iron, machinery, and miscellaneous. One indefatigable weaver, it is said, has woven the four Gospels on cloth, to exhibit as a specimen of his skill.

BRAKE, or BREAK. This name is given by machinists to a contrivance for retarding or arresting motion, by creating an amount of friction too great for the moving power, or for the momentum of the machine, in cases where the moving power is suspended, to overcome. Brakes generally consist of blocks of wood so connected with a system of levers or screws that they may be pressed firmly against the periphery of a wheel mounted upon the main axle of the machine; but in some cases, instead of a block of wood, a strap or belt of iron, of sufficient length to embrace one-half of the periphery of the brake-wheel, or a series of small blocks of wood attached to the concave surface of such a strap is used.

Among the many contrivances for attaining safety in railway travelling, self-acting brakes have been devised, which would begin to act as soon as the buffers of two adjacent carriages were pressed together, and would arrest the revolution of the wheels with a force directly proportionate to the force with which the carriages ran together; but it is doubtful whether the inconvenience of such an apparatus under certain circumstances would not more than counterbalance the anticipated advantages. It is however a fair field for invention, and many patents have recently been obtained in relation to this matter.

BRAMAH, JOSEPH, occupies a distinguished rank as the maker of delicate pieces of mechanism. He was born in 1749. He established himself as a cabinet-maker in London, and afterwards obtained celebrity as the inventor of important improvements in water-closets, and of an ingenious lock, which yet maintains its character as one of the most inviolable ever contrived. [Lock.] This invention was patented in 1784. He also contrived improvements in water-cocks, pumps, and fire-engines, and in 1796 patented the invaluable machine known as the Bramah press, or hydraulic press. Among his other inventions were the beer-machine, commonly used in taverns for drawing beer in the bar from barrels deposited in the cellar; improved planing-machinery; paper-making machinery; an instrument for making quill-pen nibs; and the beautiful contrivance [BANK-NOTE MACHINERY] by which bank notes are numbered with a regular succession of numbers, without the possibility of twice producing the same number. By the introduction of this last-named machine into the Bank of England the labour of 100 clerks out of 120 was dispensed with. Bramah died in 1814.

BRAMAH'S PRESS. [HYDRAULICS.]

BRANDENBURG, a province of Prussia, possesses considerable manufactures in many of the towns. The first manufactures were established by the Huguenot refugees, who received cordial assistance from the government, and were liberally seconded by it in their outset. The woollen manufactures, which are the most important, are established in most of the towns; those for the finer sorts of goods are at Luckenwalde, Züllichau, Kottbus, and Guben; kerseymeres and merino cloths are made in Berlin, where woollen yarns are spun on a large scale by steam-machinery. The manufactures of linens, chiefly of the middling and coarser sorts, is extensively carried on in the Lusatian districts and the circle of Frankfort. Tanneries, paper-mills, sugar-refineries, and manufactures of tobacco, glass, porcelain, earthenware, iron, steel, copper and gunpowder, are among the industrial establishments of the province. The Berlin iron ornaments have become particularly celebrated.

BRANDY. This well known liquid is the alcoholic or spirituous portion of wine, separated from the aqueous part, the colouring matter, &c., by distillation. The word is of German origin, and in its German form, *brantwein*, signifies burnt wine, or wine that has undergone the action of fire. Brandies, however, have been made from potatoes, carrots, beet root, pears, and other vegetable substances; but they are all inferior to true brandy. Brandy is prepared in most wine countries, but that of France is the most esteemed. It is procured not only by distilling the wine itself, but also by fermenting and distilling the *marc* or residue of the pressings of the grape. It is procured indifferently from red or white wine; and different wines yield very different proportions of it, the strongest of course giving the largest quantity. Brandy obtained from marc has a more acrid flavour than that from wine, which appears to be occasioned by an oil contained in the skin of the grape, which when separated proves so acrid that a single drop would deteriorate several gallons of good brandy. The celebrated brandy of Cognac, a town in the department of Charente, and that brought from Andraye, seem to owe their excellence to being made from white wine, so fermented as not to be impregnated with this oil. Like other spirit, brandy is colourless when recently distilled. By mere keeping however, owing probably to some change in the soluble matter contained in it, it acquires a slight colour, which is much increased by keeping in casks, and is made of the required intensity by the addition of burnt sugar, or other colouring matter.

The production of brandy, so far as obtaining the alcoholic principle is concerned, is described under DISTILLATION.

Although brandy drinkers despise or affect to despise patent or British brandy, yet it is a question whether this may not be quite as pure and strong as much that goes by the name of foreign brandy. So enormous is the duty paid on foreign brandy, that the French manufacturers are induced to strengthen it artificially by spirits of wine, and the English dealers to increase its bulk by water and other additions. Foreign brandy ought to be a little 'over proof;' but it is frequently 12 to 15 degrees below proof. Dr. Normandy, in his recent work on adulteration, has the following remarks on the worst or really fraudulent brandy :—

'Brandy, when newly distilled, is white, but that met with in commerce is always of a yellowish, brown, or dark brown colour, which is due to the presence of some extractive matter, and of tannic acid, which it has dissolved from the oak casks in which it has been kept for a long time. But in order to simulate this colour of genuine brandy, the brandy of commerce is nothing else than new brandy or alcohol, at once converted apparently into old brandy by means of caramel, or burnt sugar.'

British brandy, for which patents have been obtained by many English distillers, is the result of numerous attempts to produce, from malt-spirit, a liquor that shall bear much resemblance to foreign brandy. The best malt-spirit is the basis of all the British brandies; and the flavour, colour, and degree of strength, are brought about by the addition of some among the following long list of ingredients: water, red tartar, acetic ether, French vinegar, French plums, wine-bottoms, tincture of catechu, oak shavings, bitter almonds, burnt sugar, tincture of vanilla, oil of cassia, rum, &c.: each manufacturer having a favourite recipe of his own. It is said that where black tea is cheap, as in America, it is often employed to give an imitative brandy-roughness to coloured spirits.

Whatever may be the quantity of imitative brandy made in England, the importation of foreign brandy still continues very large. In 1849 it amounted to no less than 4,480,306 gallons.

Brandy is an ingredient in a large number of cordials and liqueurs; such as cherry-brandy, carraway brandy, lemon brandy, orange brandy, peach brandy, raspberry brandy, and the like. They all bear a family resemblance in so far as they consist of brandy, flavoured by the fruits or seeds whose name they bear, sweetened with sugar, and rendered fragrant with spices.

BRASS. This very valuable metal is an alloy of copper and zinc, which, from the remotest antiquity, has been extensively applied to useful and ornamental purposes. It was made long before zinc was obtained in its metallic form, by exposing grain or bean copper, which was produced by pouring melted copper into water, or copper clippings, to great heat in crucibles with calcined and powdered calamine, a native carbonate of zinc and charcoal; but in 1781 James Emerson obtained a patent for making brass in a more direct way, by melting together its constituent metals; and this mode is now generally practised. The proportions of the two metals vary much in different kinds of brass, but nearly two-thirds copper and one-third zinc appears to be best for ordinary purposes. M. Machts, of Vienna, has recently found that brass made in a peculiar way from 60 per cent of copper, and 40 of zinc possesses a valuable degree of malleability. Prince's, or Prince Rupert's metal, tombac, or tombak, pinchbeck, similor, Mannheim gold, and several other alloys of similar character, are only varieties of brass, the several proportions of which however are variously given by different writers.

The general properties of brass are, a fine yellow colour, susceptibility of a high polish, and being only superficially acted upon by the air. It is brittle at a high temperature, but very malleable and ductile when cold. Its specific gravity is greater than that deducible from the specific gravities of its constituent metals. It is more fusible, a worse conductor of heat, and harder than copper. The facility with which it may be cast, and turned in a lathe, or otherwise worked, renders it peculiarly useful in the construction of mathematical instruments, and the smaller parts of machinery. Brass wire is extensively used in pin-making, and for various other purposes. *Latten* is a name sometimes given to thin sheets of rolled brass; and *Dutch metal* or *Dutch gold* is brass beaten out into very thin leaves.

It has been much contested whether brass is a true chemical compound of copper and zinc, or merely a mechanical mixture. Since the rise of electro-metallurgy, many experimenters have stated that they have precipitated or deposited brass from liquid solution, which, it is calculated, could not occur if the two component metals were merely an alloy, and not a chemical compound. The subject has not yet been definitely settled.

A mode of using sheet brass or other metal for ornamental purposes was introduced a few years ago, in which the appearance of solid metal might be obtained without the weight, by using a wooden core to place the sheet metal upon. The method is useful for making cornice-poles, mouldings, or other articles of continuous form and pattern. The wood is first shaped, by planes and other tools, to the required pattern; the sheet metal is placed upon it; and the two together are drawn through a suitable die, which unites them by driving the edges of the metal into the substance of the wood. If the pattern be a plain one, it is struck down upon the wood by the die through which it passes; but if the pattern be full and complicated, it is imparted to the sheet metal by swaging tools and dies, previous to the application of the metal to the surface of the wood.

The brass manufacture is one of the most important of the Birmingham branches of industry. No less than thirty manufacturers of that town have announced their intention to present specimens at the forthcoming grand Exhibition, in the departments of brass bedsteads, lamps, gas furniture, tubing, ornaments, &c.

Brass work was exported in 1849 to the value of 114,000*l*.

BRAZIL. This vast country is rich in products useful in the arts and manufactures. Besides the ordinary kinds of vegetable food, the natives cultivate the cocoa-plant, the maté-plant, coffee, sugar, cotton, tobacco, indigo, ginger, pepper, cinnamon, cloves, vanilla, sarsaparilla, caoutchouc, copaiva, copal, various fruits and also various dye-plants and timber-trees. The herds of horned cattle are immense; and their produce, consisting, besides live stock, of hides, jerked beef, tallow, horns, and horn tips, is exported in great quantities. As soon as the animals are skinned, the hides are spread on the ground, slightly salted, and dried in the sun. The flesh is cut into thin slices, salted, and dried in the air, for consumption in the northern provinces. A little butter and cheese is made.

The Brazilians produce many useful substances from the animals by which they are surrounded. They prepare spermaceti and oil from some of their fish; they salt and dry many of their larger fish, to serve as a store of provisions; they make sausages from the flesh of the manati, a peculiar kind of fish; they produce a fatty substance from the eggs of turtles by roasting; and they fry one species of ant as an article of food.

The mineral wealth of Brazil is considerable, but limited to a few articles, of which the chief are gold and iron, diamonds and topazes, and salt. Before the beginning of the last century the quantity of gold obtained was inconsiderable, but it increased rapidly. The greatest quantity was found between 1753 and 1763, but it afterwards decreased. The grains of gold in the sand being nearly exhausted, and capital being wanted to work the veins in the mountains, the produce fell off; but, since the introduction of British capital into some of the provinces, the produce of the mines has increased. Iron is very abundant: in some places there are whole mountains of ore; but up to the present time it has been worked on an extensive scale only in two or three places. In 1843 a government iron-foundry was abandoned as an unprofitable speculation. No *silver* has been found, and only slight indications of *copper*, *tin*, and *quicksilver*. *Platinum* occurs in some places. *Lead* and *cobalt* are more common.

No country probably is richer in diamonds than Brazil, but hitherto they have only been found in the rivers. The diamond district, or the district of Tejuco, where by far the greatest quantity of diamonds has been found, is situated under 18° S. lat.; and here many hundreds of persons are employed by the government in searching for diamonds. In about a century from 1730 to 1830, it is supposed that the diamonds found must have been worth three millions sterling. In another diamond district, that of Abaeté, was found in 1791 the great diamond weighing 138½ carats, one of the largest in the world. Diamonds are also found in other districts of Brazil.

The Brazilians obtain their salt from salt steppes or plains. There are here and there patches of salt efflorescence on the surface of the ground. There are also salt springs, and salt steppes which yield salt after a shower of rain.

Internal communication in Brazil is in a very imperfect state. The roads are few, and mostly bad. The rivers offer a fine field for traffic enterprise, but the country is not in a state to develope its own advantages. Steam transit has been partially introduced on one or two of the rivers.

The foreign commerce of Brazil is very large. The vessels of all nations are admitted on the same conditions, and their cargoes pay the same duties. The most important articles of exportation are sugar, coffee, and cotton. The exportation of cocoa, hides, tobacco, rice, horns and horn-tips, dye-woods, sarsaparilla, and indian-rubber is also considerable. The smaller articles are isinglass, indigo, castor beans, castor-oil, and different drugs. The chief ports visited by European vessels are S. Pedro, Santos, Rio Janeiro, Bahia, Pernambuco, Maranhao, Parà, Aracaty, Seara, and Parahyba. Rio Janeiro is the chief place of export for coffee, Bahia for sugar, and Pernambuco for cotton.

The British produce and manufactures sent to Brazil in 1849 exceeded 2,000,000*l.* in value. The exports from Brazil amount to four or five millions sterling per annum; they are sent to almost every part of Europe and America, and to many African and Asiatic ports.

BRAZIL NUTS. There is in the vast forests on the banks of the Orinoco, a genus of trees, of large size, called *Bertholletia.* Its stem averages a hundred feet in height, and two feet in diameter, not branching till near the top, whence its boughs hang down in a graceful manner. The fruit is figured and described by Humboldt as a spherical case, as big as a man's head, with four cells, in each of which are six or eight nuts; its shell is rugged and furrowed, and covered with a rind of a green colour. The nuts are irregularly triangular bodies, having a hard shell, which is very much wrinkled, and which is fixed to a central placenta by their lower end. The seed is a firm oily almond, of a pure white colour. 'The Portuguese of Para,' says Humboldt, 'have for a long time driven a great trade with the nuts of this tree, which the Spaniards call *almendron;* they send cargoes to French Guiana, whence they are shipped for England and Lisbon. The kernels yield a large quantity of oil, well suited for lamps.' They are sold in England under the name of Brazil Nuts.

BRAZIL WOOD, is much used in dyeing. A decoction is made from the wood by the action of hot water; and this decoction, by various modes of using, is made to impart a beautiful red-dye to cottons, linens, silks, and woollens.

Another name for this wood is *sapan.* It is brought from Brazil and is the wood of the *cæsalpinia crista.* From 3,000 to 4,000 tons are imported annually.

BREAD and BAKING. There is a marked characteristic which separates bread into two kinds:— *biscuit* bread, which is made without fermentation, and is compact, heavy, and hard; and *loaf* bread, which is fermented, and thereby rendered porous, light, and soft. The flour of barley, oats, and rye, is used as well as that of wheat for making bread; but our brief details will apply more especially to wheaten bread, which is the most extensively used in England, and in which the properties of perfect bread are most distinctly exhibited.

In making biscuit bread [BISCUIT], no chemical change is effected: the operation being the merely mechanical one of moistening particles of flour so as to cause them to adhere together, and to remain in one mass by the subsequent process of baking. The operation of making fermented bread is far less simple.

Wheat flour consists of *starch* and *gluten*, with a very small proportion of other substances: and the relative proportions of these constituents vary in different kinds of corn. A mode of comparing the qualities of flour in this respect has been already described. [ALEUROMETER.]

When flour is mixed with water, it forms the well-known paste called *dough*, which ferments if left in a moderately warm place. During this fermentation, carbonic acid gas is evolved; and this gas, in its natural tendency to escape into the air, is arrested in its progress through the dough by the adhesiveness of the gluten, and consequently forms the numerous cavities we see in fermented bread. These are more numerous, and consequently the bread is lighter, when wheat flour is used than when the flour of oats or rye, which contains less gluten, is employed. This natural process of fermentation however is slow and tedious, and is liable to impart a disagreeable flavour to the bread; to remedy which, the custom of accelerating the fermentation by adding a small quantity of dough in a state of strong fermentation, called *leaven*, was introduced. The substitution of *yest* (the frothy scum which rises on the surface of beer during its fermentation,) for this leaven is a further improvement.

In the ordinary mode of making bread the water is used at a temperature of from 90° to 100°, a little salt and yest is mixed with it, and then a quantity of flour. The substance thus produced is covered up and set aside in a warm situation: this part of the process being called *setting the sponge*. Within an hour the progress of fermentation is manifested by the swelling and heaving of the sponge; and this process is allowed to proceed, with the occasional dropping or sinking of the dough when the confined gas becomes so powerful as to force a way for escape, until a period dictated by experience as that beyond which further fermentation would be hazardous. The baker then adds the remaining flour, water, and salt, and incorporates all the materials thoroughly together by long and laborious kneading. When this has been continued until the dough will receive a smart pressure of the hand without adhering to it, it is again left to ferment for a few hours, and afterwards kneaded more gently, in order so to distribute the gas engendered within it as to make the bread equally light and porous throughout. It is then formed into loaves, which being set aside for an hour or two, expand to about double their original volume: and these loaves are finally baked in the oven, by which process they enlarge still more in bulk, not by the continuance of fermentation, but by the expansion of the gas already formed, through the effect of heat. The result is a loaf composed of an infinite number of cellules filled with carbonic acid gas, and lined with a glutinous membrane.

When flour is converted into bread, it is found on leaving the oven to have increased from 28 to 34 per cent. in weight; but bread which has gained 28lbs. will lose about 4lbs. within thirty-six hours after leaving the oven. The season of growth, the age of the flour, and other circumstances, affect the quantity of bread obtainable from a given weight of flour; but generally speaking the better the flour is, and the older, within certain limits, the greater will be the quantity of bread.

The *panary* fermentation, or the fermentation which dough undergoes, is nearly identical with *vinous* fermentation; a little alcohol being produced by it. Hence arose a notable project, a few years ago, for *saving the spirit* produced in bread making; a sum of 20,000*l.* was spent in establishing a bakery at Chelsea but it was soon found that the projectors had totally misconceived the chemistry of their subject; while neighbouring bakers, by advertising '*bread with the gin in it*,' contrived to throw the gin-less bread quite out of popular favour.

Under ordinary circumstances, no machinery is employed in bread making in England. About 20 years ago Mr. Clayton obtained a patent for a rotatory kneading machine: in the interior of which knives were placed diagonally; and other mixing and kneading machines have since been invented; but the hand method remains still almost exclusively in force in this country. Our French neighbours understand these things better: they apply more science to the chemistry of eating and drinking. The mixing and kneading are generally effected by hand: but they are more carefully attended to than in England. There is, however, a machine-bakery, patented at Paris by M. Mouchot, of which Dumas gives a description: the lifting of the flour into the troughs, the admission of water, the mixing, the kneading, the baking—all are effected by the aid of efficient machinery.

A machine for baking bread by steam was introduced into France about five years ago. It consists principally of two concentric cylinders, the inner one of which has numerous perforations. The dough is placed in the inner cylinder, and steam is admitted to the space between the two cylinders. Half an hour is said to be sufficient for the heat of the steam to bake the bread; but it would appear that there ought to be some mode of drying the bread after this process.

An ingenious mode of baking biscuits is described in the 'Mechanics Magazine' (No. 981) as having been invented by Mr. Deucale, an American, and practised in New York. A brick oven stands in the middle of the bakehouse, 12 feet long, 6 feet wide, and 4 feet high. The top has no opening whatever. The front has an opening near the ground, with a metal door, through which the fuel is introduced and made to cover the entire area of the floor of the oven. About a foot above the furnace door is an opening six or eight inches high and the whole width of the oven; a similar opening exists at the back of the oven. Near each opening is a wooden cylinder; and round both cylinders a wire latticework is tightly coiled, so as to form an endless cloth stretching horizontally within and across the oven, over the fire. The dough and biscuits being ranged in a row along the front edge of the wire-cloth, the baker turns a winch hand and winds them into the oven; this he does row after row, until, by the time the first row has reached the back of the oven, the biscuits in that row are properly baked. This method presents a good deal of analogy to that described under BISCUIT.

In respect to *ovens*, considerable improvements have been introduced within the last few years; instead of placing fuel *in* the oven, it is placed on one side, and flues are so arranged as to heat the oven with less waste, more quickly, and with more cleanliness than on the old method.

Of the condition of the *bakers* much has been said lately which tends to show that there is sad want of improvement; Dr. Guy's Report on this subject gives a gloomy picture of the effects of night work on the journeymen bakers. Nor is the genuineness of the bread produced quite so undeniable as one might wish. Indeed the public has been a little scared at the long list of objectionables used to adulterate bread—damaged wheat, beans, peas, carbonate of ammonia, potatoes, plaster of Paris, chalk, pipeclay, burnt bones, are all said occasionally to take part in the manufacture of what ought to be wheaten bread. There is a double mischief in all this: it is a robbery in itself; and it leads to the honest as well as the dishonest being suspected by those whose suspicions are aroused, but who have neither inclination nor skill to analyse their bread.

The varieties of bread used only in a small degree are numerous. There are bran bread, French soup bread, grain bread, household bread, Iceland moss bread, leavened bread, potato bread, &c.—all of which have peculiarities either in the ingredients or in the mode of making.

BREAD FRUIT. A Bread-Fruit is a fig turned inside out, and much larger in all its parts; that is to say, the flowers which form the bread-fruit and fig grow, in both cases, upon a fleshy receptacle; but in the former the receptacle is solid and bears its flowers externally, while in the latter it is hollow and bears its flowers internally.

The bread-fruit (*Artocarpus incisa*) is a native of the South Sea Islands, and of many parts of the Indian Archipelago. The fruit is green and of considerable size, equalling a melon of the larger kind in dimensions, and is of many different forms. The nuts, when roasted, are said to be as good as the best chesnuts; but it is principally for the fleshy receptacle that it is valued. When roasted it becomes soft, tender, and white, resembling the crumb of a loaf; but it must be eaten new, or it becomes hard and difficult to swallow. It forms so important a part of the support of the South Sea Islanders that it was introduced by the British Government into the West Indies, where it is still cultivated, and whence it has been carried to the continent of America. It does not appear, however, equal to the plantain as an article of human food.

BREAKWATER. The Plymouth breakwater is a public work on which we justly pride ourselves. It was commenced in 1812, and is formed of stone procured from the shores of the harbour. The quarrying of the stone, the conveyance into the vessels by a railway, the dropping of the stones into the sea by opening trap doors in the vessels, the gradual accumulation of the vast heap, and the dressing of the surface to the required form, are all remarkable operations. The works are not even yet completed; for so late as August, 1850, the admiralty advertised for 130,000 cubic feet of dressed limestone, to be supplied during 1851. The breakwater is a straight line of stone-work with two wings inclined a little towards the north; the straight portion is about 1000 yards in length, and the wings 350 yards each. The width at the bed of the sea is 300 to 400 feet; but only 50 at high water level. The upper surface is horizontal, and about 2 feet above high water spring tide. The inner face has a slope of 2 to 1, and the outer face a slope of 5 to 1. The coarse rubble contained in the structure, up to the present time, exceeds 3,000,000 tons; the dressed masonry 2,500,000 tons. Upwards of 330,000 tons were deposited in one year (1816). The works (which were under the late John Rennie until 1821, and since under the present Sir John) have cost about 1,500,000*l.*; and seldom has public money been more advantageously expended.

The breakwater at Cherbourg, which is so honourable to our French neighbours, and which attracted so much the attention of our naval officers on a recent occasion, is briefly described in another article. [CHERBOURG.]

The breakwater at Portland, now being constructed by Mr. Rendel, will shelter an area of 1822 acres. From the eastern point of the island of Portland, it will run out 1,500 feet in an easterly direction, and then 6,000 feet north-eastward; but at the angle between these two portions will be an opening about 500 feet wide, for the entrance of steamers and small craft. More than 7,000 feet of the entire length will be built in 5 to 8½ fathoms depth at low water. From the large store of stone in the island, the facility of transport, and the employment of convict labour, it is estimated that this great work may be completed for 560,000*l.* A railway, with three inclines, drums, wire-ropes, &c., are employed to raise and lower the waggons, and to carry stones from the top of the island to the spot where they are dropped into the sea.

The determination of the government to construct harbours of refuge has led to the promulgation of many plans for breakwaters. A few of these we shall briefly glance at, as well as others suggested somewhat earlier.

Captain Tayler's Floating Breakwater was introduced to public notice in 1838. It consists of a frame-work or caisson of timber, moored and shackled, so as to yield to the violence of the sea, and to admit the water to pass under, over, and through it. The circumstances which, to the inventor's mind, seem to point out this as a useful form, are the following: 1st. It divides and breaks the waves, and reduces them to a harmless state; converting all that happens to lie within a crescent of such breakwaters to still or smooth water. 2nd. It is free from the objections which often pertain to solid breakwaters, in so far as they tend to the filling up or obstructing of harbours and channels by accumulation of sand and mud. 3rd. It can be laid down on any part of the coast, so as to form a harbour where none can be formed by ordinary means. 4th. It can be constructed and kept in repair at a mere fraction of the cost of an ordinary breakwater. These are high claims, but they have not yet met with a favourable reception. According to the specification of the patent, the timber-framed caissons are to vary in shape and form according to the depth and nature of the sea wherein they are to be moored; but, as a general rule, about one-third of the mass is above water. As it is optional to make the structure of any convenient dimensions, many such may be chained or otherwise fastened end to end, so as to form a lengthened straight or curved breakwater.

Another plan recently proposed consists in placing a number of spars upright in the sea, three or four feet apart: the spars being five or six inches square, and of a length (about 24 feet) sufficient to reach the whole depth of the deepest waves. A heavy stone or any kind of mooring anchor is lowered to the bottom of the sea beneath each spar, and the spar is connected with this by a chain. Each spar yields easily to any forcible pressure from the sea, since the small chain at bottom acts as a hinge; but it will soon recover its vertical direction, which it maintains by virtue of the wood being of less specific gravity than sea-water. How many rows of such spars would be necessary to check the force of a sea, would in all probability depend on the nature of the locality.

Captain Vetch (in Weale's *Quarterly Papers*, 1843) advocates a vertical construction of breakwaters, instead of a sloping face towards the sea. His plan consists in a peculiar application of wrought iron rods, which pass vertically through the water, and are supported by horizontal iron frames, through orifices in which the rods pass. The frames and rods receive lateral support by other rods placed in a sloping position, in a double row on the two faces of the breakwater.

In 1848 Mr. W. H. Smith published a small pamphlet relating to Harbours of Refuge, in which he recommends the use of a peculiar kind of breakwater. It consists of a hollow framework of timber, which is secured to the ground by screw-piles, such as those employed in Mitchell's screw-pile lighthouses; the framework is free to oscillate on these piles, within certain limits, which are determined by mooring blocks, and counterbalance weights.

Captain Sleigh's proposed breakwater consists of a series of sloping or oblique platforms supported by floating hollow vessels or caissons; by which the platforms are always maintained in an oblique position, and are enabled to rise and fall with the tide. These floating vessels and sloping platforms are to be so arranged as to form sea and wind barriers for sheltering ships, pier-heads, and bridges; they may be made of any dimensions, and any convenient number of them may be ranged end to end, so as to form either a straight or a curved line, according to the size and shape of the spot to be sheltered.

A singular form of Breakwater was suggested by Captain Norton a few years ago. He had observed, that where the *lotus* plant grows on a lake or pond, if a strong wind ruffles the water on one side of the leaf, the water is comparatively smooth on the other side: resulting from the wind having no hold on the broad expanse of the leaves. He had also observed, after a storm at sea, the solid timbers of a wrecked vessel splintered in pieces by being driven against the shore; while a wicker basket escaped uninjured. These two facts suggested the idea of constructing a floating breakwater of *osiers*. A model of such a machine was exhibited at the Polytechnic Institution in 1843.

Engineers of eminence, both military and civil, are at present engaged in a discussion whether *vertical* or *sloped* faces are best for sea walls and breakwaters. So much is this an undecided question, that the recent injury to the new works at Dover Harbour is appealed to, to afford evidence on one side or the other.

BREMEN, one of the free Hanseatic towns, owes its prosperity to the navigable river (the Weser) on which it stands. It is the entrepôt for imports of all the countries bordering on the Weser, and especially for Hanover, Oldenburg, and Hesse-Cassel. A railroad from Bremen to Hanover was opened in Dec. 1847. Large vessels go up the river only as far as Bremerlehe, 28 miles below Bremen; there they discharge their cargoes in a new harbour called Bremerhaven. Ships of 200 to 250 tons unload at Vegesack, 13 miles below Bremen; and vessels of seven or eight feet draft go quite up to the town. Cargoes brought to Bremerhaven and Vegesack are forwarded to Bremen by lighters and boats. Bremen is a place of great resort for the warehousing and transit of foreign and German goods; it has a bank, discount office, and several insurance companies. The ships of Bremen have been largely engaged of late years in carrying out German emigrants to America. The chief imports are raw cotton, cotton yarn, sugar, coffee, tea, tobacco, dye-stuffs, and other colonial produce. The exports consist of these same items, and linens, grain, oak-bark, salt meat, hides, seeds, rags, wool, woollen goods, and wine. The vessels which arrive annually are 1100 or 1200 in number, many of them of large tonnage; and they bring to the city an immense quantity of merchandize. The town has several sugar-refineries, above 100 distilleries, tanyards, soaperies, cordage and canvas factories, cotton-mills, bleach-works, tobacco factories, &c.

BRE'SCIA is rich in most of those articles of produce, such as silk, oil, wine, and fruit, which will come under our notice in the article LOMBARDY.

BRESLAU, the capital of the Prussian province of Silesia, is highly favoured by nature for a trading depôt; its central position among the manufacturing districts of Silesia, its facilities for trade by means of internal navigation, and by railroads which connect it with Vienna, Prague, Dresden, Leipzig, Hanover, Hamburg, Berlin, and Stettin, render it one of the most thriving manufacturing and commercial cities of Europe. It is an entrepôt for the fine and coarse woollens, cottons, linens, silks, hardwares, glass, wools, hemp, and flax of Silesia; for the wines of Hungary and all kinds of colonial produce. The oxen of the Ukraine and Moldavia, the corn and cattle of Silesia, and the produce of its own distilleries, tanyards, typefoundries, and all those manufactures which it has in common with other large towns, find a regular sale at Breslau. Four fairs are held in the year, those for wool are held in the early part of June and October. The average quantity of wool sold at the June fairs amounts to 7,000,000 lbs.

It is interesting to note, as a proof of the tendency of trade to penetrate in all directions, that at the Michaelmas wool-fair at Breslau, in 1850, more than 300 bales of *Australian* wool were sold, and were readily bought by the manufacturers of the Zollverein or Customs' Union district of Germany.

BREST is a fortress and naval station of the first class. There are handsome quays, ship-building yards, extensive storehouses, rope-walks, and barracks; but as its works relate wholly to defence and not to commerce, we need not describe them here.

BREWING and BREWERIES. Whether ale or beer be the object of the brewer's attention, the *chemistry* of the manufacture is pretty nearly the same. It consists in the process of extracting a saccharine solution from grain, and in converting that solution into a fermented and spirituous beverage. This art, although a perfectly chemical one in nearly all its stages, has not until recent times been indebted to chemistry for any of the improvements which have been made in its details.

In brewing the various beers, as ale, porter, and table-ale, two kinds of malt are employed, the *pale* and the *brown*. The first is used for ales, and for the finer qualities the malt is dried very pale indeed; the brown malt is used for porters and stouts. Roasted or black malt is used as a colouring material, in place of burnt sugar.

The malt is first ground or crushed; and the grist or ground malt being prepared, the next part of the process is the mashing. The *mash-tun*, or vessel in which this operation is carried on, is usually of wood, varying in size according to the quantity of malt to be wetted, and having two or more taps in the bottom. From one to two inches above this bottom is a false bottom pierced full of small holes, on which the grist is placed; the hot water is then admitted, and the grist is intimately mixed with the water. For this purpose machinery is used to stir it about, and cause it to assume a homogeneous consistence. The whole is then allowed to stand at rest for a certain time; and the taps being opened, the infusion, or sweet wort, is allowed to run off into a vessel called the *underback*, whence it is pumped or otherwise conveyed to the copper for boiling. When the wort has run off, the taps are closed, and a fresh quantity of hot water is run on for a second mash. When the whole of the wort is pumped into the copper, the hops are thrown in, and the boiling commences. For large coppers machinery is used to prevent the hops from settling down and burning. When the boiling is complete, the whole contents of the copper are turned into the *hop-back*, which is a large square or oblong vessel of wood or iron, having a false bottom for large brewings, and a sieve partition at the corner for small ones.

As the boiled wort drains from the hops it is allowed to run, or is pumped, into the *coolers*. These hops, when sufficiently drained, may be again boiled with a second copper of wort, or with the return wort or table-beer. The coolers are large shallow vessels, placed in as open a part of the brewery as possible, so as to command a free current of air over the whole of their surface: they may be constructed of either wood or iron. Fans and blowers are sometimes used to assist the rapidity of this part of the process. When sufficiently cool, the wort is allowed to run into the fermenting tun.

The wort is next fermented in a large vessel called a *gyle*, or fermenting *tun*. As soon as the wort begins to run from the coolers, and when a sufficient quantity is in the tun, the yest is added. When the fermentation has arrived at a certain point of attenuation, that is, when a certain quantity of the saccharine matter of the wort has been converted into alcohol or spirit, it is cleansed from the yest; for this purpose it is either run into smaller vessels, such as casks or rounds, or the yesty head is skimmed off from the top; and this is repeated at intervals until the beer is clean. This operation of skimming is generally confined to the cleansing of ales. The *casks* are simply filled with the fermenting beer, and so arranged as to be always kept quite full, with a trough or stillion to catch the yest as it works out at the orifice of these vessels. The beer, being thus cleansed from all the yest, is now either racked directly into casks as for ale, or run into vats prepared for it. On the large scale a large vessel is first used, into which the beer intended to be vatted is allowed to run so as to be perfectly well mixed, and also to deposit a further portion of yest by standing. The beer is by this means also rendered flat, which is necessary for stock or store beer that is to be kept some time before coming into use.

The last operation the beer has to undergo is the fining, or clearing, which is sometimes done by the brewer, sometimes by the publican. The fining material consists of isinglass, or other gelatinous matter, dissolved in acid beer, or sours, which, having been added to the ale or beer, agglutinates or collects together all the lighter floating matters which render the beer thick, and ultimately falls to the bottom of the vessel with them, leaving the beer clear and transparent.

Such is a simple outline of the processes, whether bitter or mild, strong or weak beverage is to be brewed, and whether the scale of operations be large or small. The reader will have no difficulty in conceiving that the mechanism and details of the processes must vary greatly, although the chemical principles may remain the same. In Bavaria the brewing of beer is one of the chief, perhaps *the* chief, manufacture; for the Germans are resolute beer drinkers. They have black beer, white beer, brown beer, thin beer, strong beer, double beer, bitter beer—differences which we attempt, though not very successfully, to indicate by our names *ale*, *beer*, *porter*, *stout*, &c. Bavarian beer and Scotch ale differ from English beers and ales in being fermented at lower temperatures. *Ale*, in England, is brewed from paler malt than *beer*; *porter* is brewed from pale malt coloured with burnt malt; *stout* is only a superior kind of porter; *table-beer* is simply poor or weak beer. Malt is the proper material for yielding beer; but imitative beers are brewed from bran, potatoes, spruce, sugar, and treacle.

A few flavouring and sweetening ingredients are recognized and allowable in brewing; but the world knows very little of the adulterations to which beer is too often subjected. Quassia, gentian, wormwood, broom-top, to impart bitterness; capsicum, ginger, coriander, orange peel, caraway, to give pungency; opium, cocculus indicus, nux vomica, tobacco, poppy, henbane, to intoxicate; molasses, sugar, treacle, as substitutes for malt; sulphuric acid, alum, vitriol, salt, to impart various properties —all are suspected, and more than suspected, of playing a part in the manufacture of some of those beverages which occasionally go by the name of beer. The Excise have battled hard against these difficulties; but with only partial success.

Mr. Tizard, a brewer of Birmingham, has suggested a remarkable arrangement for fermenting the beer. He proposes the use of a subterranean fermenting room, sunk to such a depth as to have a uniform temperature from 45° to 52° at all hours and seasons. This, in our country would be a depth of about 70 or 80 feet. The fermenting vessels are surrounded with cold water in this subterranean chamber. The cooled wort is conveyed by a pipe down into the vessel; and after the processes of fermenting, cleansing, and fining, it is drawn up again through racking taps, which only just dip below the surface of the liquid, so as not to disturb the lees of the liquor.

A cooler for brewing, introduced by Mr. Davidson, acts in the following way. The wort is pumped up at a slow and regulated speed into a recipient at the top of the machine; it there divides into a series of thin films or streams, and trickles down the inside of a number of thin metallic tubes, set vertically. An upward current of air passes through these tubes, meeting and cooling the hot wort.

Various other improvements are frequently being introduced or suggested; but we must hasten to say a few words of the vast establishments wherein brewing is sometimes conducted, and of which Messrs. Barclay and Perkins' Porter Brewery is the most notable specimen.

This large establishment covers many acres, and contains so many court yards and buildings surrounding them, that it almost requires a map to render the arrangement intelligible. Here is the vast 'tun-room' or fermenting house; north-east of this, on the river side, is the wharf for landing the malt and for shipping the beer; westward of the wharf are the immense malt warehouses; nearer at hand are the steam-engine apparatus, the water reservoir, the cooperage, the ale and porter brewhouses, the fining house, the store vaults, the splendid stables for the dray-horses.—Such are the objects which present themselves, over an area of eight or nine acres. And when we examine them more closely, the details themselves are vast. Everything is on a large scale. The water cisterns are 30 feet long by 20 wide; the malt-bins, two dozen in number, are each large enough to contain an ordinary three-storied house; the great brewhouse is nearly as large as Westminster Hall; the copper vessels for boiling contain 12,000 gallons each; the store of beer always on hand requires 150 vats, of an average capacity of 30,000 gallons each; one particular vat contains 100,000 gallons, and weighs when full 500 tons; the number of butts, puncheons, and barrels, belonging to the establishment exceeds 60,000; about 200 horses are kept, who have stables arranged with all scientific appliances, and a veterinary surgeon on their especial behoof.

BRICK. The ancients used bricks both baked and simply dried in the sun. Those found in the ruins of Babylon [BABYLON] are among the oldest specimens existing. The Egyptians used sun-dried bricks, and the process of making them is represented in their paintings. The Greek bricks appear to have been used simply dried. Roman bricks were very thin in proportion to their length and breadth, and were well burnt.

In making ordinary English bricks, the top soil, or *encallow*, is first removed from the clay, which is dug and turned over in the winter. Exposure to wet and frost prepares it for use by the spring, when fine ashes are added to it in the proportion of one-fifth ashes to four-fifths clay, or 60 chaldrons to 240 cubic yards, which will make 100,000 bricks. When much sand is mixed with the clay, forming what is called a mild earth, a smaller proportion of ashes may be used. This quantity requires also the addition of about 15 chaldrons, or, if mild, of about 12 chaldrons of *breeze*, which is a kind of coarse coal ash, separated by sifting, to aid the burning. The clay and ashes being well mixed by digging, watering, and raking backwards and forwards with a pronged hoe, the mass is removed in barrows to the *pug-mill*, which consists of an upright barrel in which a series of strong iron knives and teeth are caused to revolve by the power of a horse walking in a circular path, so as to cut and masticate the clay very thoroughly as it passes from the top of the barrel to an aperture provided for its exit at the bottom. As the clay oozes out of the mill, it is removed with a *cuckhold*, or concave shovel, and covered with sacks to prevent its drying too fast. A person called the feeder takes from the stock of clay thus prepared a piece about the size of a brick, covers it with sand, and passes it to the moulder, who throws it with some force into a wooden mould of the size and shape of the brick, which mould is previously sanded. Having filled the mould, the moulder cuts off any superfluous clay with a stick kept in a bowl of water by his side, and then removes the back and sides of the mould, after which the soft brick is carefully transferred from the bottom board of the mould to a pallet-board, and, when a sufficient number have been moulded, is conveyed with others to the *hacks*, which are long level lines raised about 4 inches from the surface of the field, and formed about 2 feet 6 inches wide. The upper surfaces of the bricks are previously sanded, and great care is taken to avoid twisting or otherwise injuring their shape in transferring them to the hacks, on which they are laid in two rows, with a little space between each to allow the free circulation of air. One double row being completed, another is put upon them, and this is continued until the bricks are piled from seven to ten high. In putting them down the workman counts them, and makes a dot with a stick in every thousandth brick. The hacks are covered with straw at night and showery weather; and in some brick-fields sheds are erected over them; but this plan is expensive, and retards the drying. When partially dried, the bricks are removed, placed diagonally, with wider apertures, and with the bottom bricks brought to the top; and after this process, which is called *skintling*, they are removed to the *kiln* or *clamp*, which is a vast pile of bricks, laid together as closely as possible, on a slightly concave foundation of brick rubbish, the raised ends of which face the north and south. On this foundation the new bricks are built up in lots or *necks*, of which the centre one, which is first erected, is vertical, while the others, owing to the concavity of the foundation, have a slight inclination towards it. Small spaces, filled with breeze, are left among the lowest courses of bricks, and flues, or *live-holes*, about the width of a brick, and from 6 to 9 feet apart, are also formed to aid the lighting of the clamp, and filled with dry bavins or wood. When full, the clamp is surrounded by old bricks, or by the driest of those newly made, and a thick layer of breeze is spread on the top. The external bricks are coated with a thin plastering of clay; and, if the weather prove wet, the kiln is protected by *loos*, or hurdles interwoven with rushes. The fire is lighted at the mouths of the flues or live-holes, which are closed when it burns well; and in favourable weather the bricks will be completely burnt in about twenty-five or thirty days, in the course of which time the cindery matter dispersed through their substance becomes gradually ignited and consumed. Such bricks as are found to be imperfectly burnt, are put into the next clamp to be burned again. Those which are sufficiently burnt are separated, according to quality, into—hard sound *stocks; place*, or inferior soft red bricks; and *burrs* or *clinkers*, which are black-looking masses of vitrified brick, of very inferior value.

Ordinary bricks are moulded in this country 10 inches long, 5 inches wide, and three inches thick, and are reduced by drying and burning to about 9 inches long, 4½ inches wide, and a proportionate thickness.

Kiln-burnt bricks, are, as their name implies, burnt in a kiln or oven instead of a clamp, and have no ashes mixed with the clay. Marl or malm stocks, which are either baked or burnt, take their name from the marl originally used in them, which has now given place to chalk. Dutch clinkers are a kind of small, hard, yellow bricks. Fire-bricks, also called Windsor bricks, are 1½ inch thick, and of a quality to resist the action of fire. Paving bricks, draining bricks, capping or coping bricks, coggin bricks, compass bricks for wells and circular works, feather-edged or thin bricks for the external parts of wooden buildings, and many other varieties of form, size, and quality, are also made. In some cases, a smooth or glazed surface is produced in the burning.

Much ingenuity has been directed, and of late years with great success, to the substitution of machinery for hand-labour in many of the processes of brick-making. The contrivances for this purpose are necessarily too complicated for description within our limits; but as a general remark it may be observed, that the increased solidity and closeness of texture obtained in bricks so made recommend them for use in the brick-work of railway arches and tunnels, which has been found in some cases subject to decay from the alternations of temperature and moisture. The comparative costliness of machine-made bricks has hitherto impeded their general use; but machinery is already very extensively employed in the manufacture of draining and other tiles and other superior articles of the brick character.

It is known that the ancients were in possession of a method of making bricks which, though having considerable strength, and a remarkable power of resisting heat, were yet of such small specific gravity that they floated on the surface of water. About the year 1790 M. Fabbroni, an Italian, suggested that these bricks were probably made of a kind of earth found in Sicily, called *mountain meal*, containing 55 per cent. of silica, 15 of magnesia, 12 of clay, 3 of lime, 1 of iron, and 14 of water. Bricks formed of this material were found to be very slow conductors of heat, and to be so light as to float in water. They are not quite so strong as common bricks, but can be made so by the addition of a little more pure clay. They unite well with lime, and resist the action of mortar. These various qualities render such a material very serviceable for the construction of various parts of ships liable to be exposed to great heat; such as stoves, cooking arrangements, steam-engine furnaces, &c.; where lightness and incombustibility are wanted. Such bricks also might be used for constructing floating-houses on ornamental waters.

The recent repeal of the brick duty has already begun to produce beneficial effects, by allowing scope for the exercise of inventive talent. The duty, which was 5*s.* 10*d.* per thousand on ordinary bricks, increased largely if the bricks were either larger in size or of superior quality; so that the maker was deterred from any departure from ordinary size and quality. The number of bricks charged with duty during the last few years, has varied from 1,200 to 1,900 millions. Since the repeal of the duty, measures have been taken to introduce brick ornaments in architecture. Messrs. Bowers of Tunstall have patented a method of making brick ornaments by which the substance assumes a much more vitrified appearance than ordinary brick. A hydraulic press is used to force the prepared clay into moulds; and the ornament is produced with a degree of sharpness equal to fine carving. It is intended to apply such bricks to the formation of cornices, mouldings, skirting-boards, finger-plates for doors, pilaster facings, ornamental archivolts, picture frames, upholsterers' fittings, &c. The surface is so hard and smooth, that it is capable of being painted, grained, or gilt.

Mr. Robert's *hollow* bricks, introduced in 1849, are valuable for many purposes where dry, warm, and light brickwork is required.

BRICKWORK. The art of the bricklayer is shown, not merely in laying and cementing his bricks, but in making them to mutually support each other. This object, which is termed *bonding*, is accomplished by breaking or distributing the joints; so that two may never come immediately over each other; and by laying some of the bricks as *stretchers*, or stretching courses, with their length in the direction of that of the wall, and others, which are called *headers*, with their length running across, or in the direction of the breadth or thickness of the wall. The bonds in most common use are *English bond*, consisting of alternate layers or courses of headers and stretchers; *Flemish bond*, in which headers and stretchers are laid alternately in the same course, the headers of one course being laid across the middle of the stretchers of the course below it; *garden-wall bond*, consisting of three stretchers and one header in the same course; and *herring-bone bond*, which is sometimes used in very thick walls, and is produced by laying the bricks at an angle of 45° with the direction of the wall, and reversing the inclination of each successive course. Whenever it is necessary, in order to prevent the *perpends*, or vertical joints, coming immediately over each other, a half, quarter, or three-quarter brick, or *bat*, is used to commence or finish a course. Walls, the thickness of which is nine inches, or equal to the length of one brick, are called single brick; those half that thickness, half-brick; and others brick and a half, two bricks, two bricks and a half, &c.

Arched and groined work requires peculiar care, and in many cases the cutting of the bricks to fit each to its particular bed; and in ordinary house-building great neatness is called for in the formation of the flat arches over doorways and windows.

Mortar, the cement usually employed for brickwork, is composed of either gray or white lime, and river, sea, or road sand mixed with water in the proportion of one part of gray lime to two and a half of sand, or one of white or chalk lime to two of sand. The dipping of the bricks in water as they are laid makes them adhere more firmly to the mortar. *Putty* is a very fine kind of mortar, made of lime and water only, used for delicate purposes, and such as the setting of rubbed or gauged arches, where the joints are visible.

The foundations of a wall are always laid broader than the superstructure, and the broader courses are termed *footings*, the projections themselves being called *set-offs*. Garden-walls are usually strengthened with piers or buttresses projecting 4½ inches, at intervals of 10 or 12 feet. When new walls are joined on to old, it is usual to take out a brick or part of a brick from every alternate corner of the old work, in order to *tooth in* the new work; and these toothings are left in the first building when it is intended to join new work to it. In many cases, also, strips of iron

hooping are laid in the horizontal joints, to afford a further bond or tie between the old and new brickwork. Brickwork is measured by the *rod* of 272 superficial feet.

Mr. Kennedy, in his 'Campaign of the Indus,' states that no brickwork he had ever seen in Europe equalled the perfection of that exhibited in the ancient tombs near Tatta. The most beautifully-chiselled stone could not surpass the sharpness of edge and angle, or the accuracy of form; whilst the substance was so perfectly homogeneous and skilfully burned, that each brick had a metallic ringing sound, and fractured with a clear surface like breaking freestone.

BRIDGE. Most countries can exhibit specimens of bridge-building. The Chinese lay claim to high antiquity in the construction of arched bridges. One at Fou-tcheou-fou is 400 yards long, about 12 yards wide, and had formerly ranges of shops upon it; and one at the æstuary of Suen-tcheou-fou is 2500 Chinese feet in length, 20 in width, and has 252 stone piers, on which is laid a roadway of huge stone blocks. Chinese bridges have pointed, semi-circular, polygonal, and semi-elliptical arches. The Romans executed many good specimens of bridge-building, some of which remain in use to the present time. Trajan's bridge over the Danube, the most stupendous work of the kind constructed by the Romans, had 20 stone piers, 60 Roman feet broad, and 150 feet, without the foundations, above the bed of the river. The Pont du Gard, near Nismes, is a remarkable example of their bridge-aqueducts. It consists at the base of a series of six arches, forming a bridge of 465 feet long; this is surmounted by a longer series of arches, extending 780 feet, to the slope of the mountains on each side; and above these is a third series, of 35 smaller arches, extending to the length of 850 feet, on the top of which is the aqueduct or channel for water. The entire height is 190 feet.

The bridges erected by the Romans in the provinces under their sway afforded models from which the art of constructing bridges extended throughout the north and west of Europe. No country possesses finer or more numerous examples than our own; in which, even before the extraordinary impulse given to this department of civil engineering by the introduction of the railway system, it has been carried to the utmost perfection. The oldest bridge now existing in England is the triangular bridge at Croyland, in Lincolnshire, which is said to have been erected about A.D., 860; it consists of three semi or half-arches, whose bases stand equidistant from each other, in the circumference of a circle, and unite at the top. Old London Bridge, which, with numerous alterations and patchings-up, remained in use until 1831, was begun in 1176, and was for several centuries covered with houses. The modern bridges across the Thames at the metropolis form noble specimens of bridge architecture and engineering; but those constructed in the last century, Westminster and Blackfriars bridges, have entailed heavy subsequent charges on account of the insufficiency of the foundations. New London Bridge is of granite, 928 feet long between the abutments, and consists of five semi-elliptical arches, of which the centre one has a span of 152 feet, while the next pair and the abutment arches are 140 and 130 feet respectively. It was commenced in 1824, and completed in 1831. Southwark Bridge is 718 feet between the abutments, and consists of three cast-iron arches each forming a segment of a very large circle; the span of the centre one being 250 feet, and of the others 210 feet each; they are supported by granite piers. Waterloo Bridge is a fine example of a flat or level bridge, with a horizontal roadway, supported by a series of arches of equal elevation. It is of granite, has nine elliptical arches of 120 feet span, and is approached by elevated roads, supported upon brick arches. The length between the abutments is 1380 feet, the river being wider at this point than it is lower down; but, including the arched approaches, the total length is 2456 feet. The cost was upwards of 1,000,000*l.* Some very fine specimens of equal-arched bridges have been erected by French engineers, of which the Pont de Neuilly, built by M. Perronnet, between 1768 and 1780, over the Seine, has five arches of 128 feet span.

The first iron bridge in England was erected in 1779 over the Severn at Coalbrook-dale; it consists of a single arch of about 100 feet span. Bishop Wearmouth iron bridge, completed in 1796, is a single arch of 240 feet span; and Sunderland iron bridge, built about the the same time, is an arch of 236 feet span, and has a clear height from low water of 60 feet to the spring and 94 feet to the centre of the arch, so that ships of 300 tons pass under it by lowering their top-gallant masts. The very important class of iron bridges in which the suspension principle is adopted are treated of under SUSPENSION-BRIDGE. Swing-bridges, and other contrivances for removing the roadway when it is necessary to allow a passage for masted vessels, constitute another class of iron bridges on which much ingenuity has been expended. In many cases such a bridge consists of two parts, which when closed meet in the centre, and which are either raised or turned aside out of the way when the water-way has to be opened. Another curious contrivance for a similar purpose is the *telescope-bridge* introduced by Mr. Rastrick, on the Brighton and Chichester Railway; in which a massive platform, more than twice as long as the water way is broad, is so mounted on wheels as to be capable of having one half either projected across the river Arun, or drawn back out of the way; an adjoining portion of the railway being laid on another moveable platform which may be rolled to one side to make way for the larger platform when it is thus pushed back from the river.

Timber bridges, which are in many cases advantageous from their cheapness, are frequently preferred by modern engineers for their peculiar fitness in cases where an imperfect foundation, or some other circumstance, renders bridges of stone, brick, or iron unsuitable; while the introduction of various methods for preserving wood from decay obviates one of the principal objections to them. By the due application of trussing, timber bridges of extraordinary span may be constructed with safety. Some such are called *pendent* or *philosophical bridges*, and many examples of this kind of structure are found in America. The Upper and Lower Schuylkill bridges, near Philadelphia, and that across the Delaware at Trenton, are among the most remarkable. The Upper Schuylkill bridge, which is also called the Colossus, consists of one very flat arch of 340 feet span. The Lower Schuylkill bridge has three arches, one of 195 and the others 150 feet span, resting on stone piers. The Trenton bridge, erected in 1819, has five arches, one of 200, two of 180, and two of 160 feet span, resting upon light stone piers. *Lattice bridges*, so called from their structure resembling lattice-work, are much used in the United States, and have been introduced in English railway engineering.

The securing of a good foundation for the piers is the point of primary importance in bridge-building. Where the ground is soft, this must be done by *piling*, or driving whole trunks of timber, pointed and shod with iron, into the earth; it is in this kind of work that Nasmyth's steam pile-driver shows its great power; and still more, perhaps, Dr. Pott's mode of sinking hollow piles by pneumatic pressure. In order to exclude the water while laying the foundations and constructing the masonry of the piers, it is usual to form in the bed of the river a *coffer-dam*, or water-tight enclosure of piling, from the interior of which the water is pumped out. To save the enormous expense of this plan *caissons* were invented; they may be compared to great tubs or flat-bottomed boats, with very strong vertical sides. One of these being floated to the spot where a pier is to be founded, a few courses of masonry are built within it, and it is sunk into the required position. The vertical sides are subsequently removed, leaving the flat bottom beneath the masonry, as a kind of floor or foundation.

An ingenious modern contrivance is the *floating bridge* contrived by Mr. Rendel in lieu of an ordinary steam ferry-boat, for which the current was found to be too strong, as a means of communication between Torpoint and the Cornwall shore, at the mouth of Plymouth harbour, and which has since been applied also to the harbours of Dartmouth, Portsmouth, and Southampton. It consists of a large flat-bottomed vessel, the deck of which is adapted to receive horses and carriages as well as foot passengers, and which is propelled by means of wheels turned by a steam-engine mounted in the vessel. These wheels, however, instead of propelling the vessel by their action upon the water, do so by taking hold, by means of protuberances formed on their circumference, of chains which are extended from shore to shore, secured at each end, but allowed to hang under water in a festoon or curve of sufficient depth to allow ships to pass over them without danger. The chains, which are not absolutely fixed at the ends, but are attached to very heavy balance weights, are lifted up by the vessel as it proceeds, and serve not only as an abutment to secure the progress of the vessel, but also to keep it in its right course.

The *high-level bridge* at Newcastle is one of the finest examples of modern bridge building. It accommodates the York and Berwick Railway, and also the ordinary road traffic. It is a double bridge, with the railway road 22 feet above the horse road. The total length is about 1,400 feet. The extreme height is 112½ feet above high water mark. There are 6 arches, each of 125 feet span, besides several land arches. The piers are of masonry; but the arches, pillars, braces, girders, and balustrades are of iron. The carriage roadway is 20 feet wide, with two foot pavements of 6 feet each. The bridge piers are no less than 131 feet high from the foundation; they are 48 feet by 16½ in the square; they are built on piles, some of which penetrate to a depth of 50 feet in the ground. The road bridge is suspended from the arches of the upper or railway bridge; thus affording a very remarkable example of the combination of two distinct principles in bridge building.

The border bridge over the Tweed at Berwick is another fine example of railway work; constituting one of the finest stone bridges in existence. The still more extraordinary Britannia tubular bridge over the Menai will come for notice in a later article. [MENAI BRIDGES.] The *hollow girder* principle, so scientifically applied in the Britannia bridge, is now much used for small railway bridges over roads and streets.

Mr. Gladstone has recently suggested the employment of wrought iron bars as a material for bridges. The astonishing strength of the angle irons and other parts of the Britannia tubular bridge, is leading engineers to the consideration of further employment of similar materials. Mr. Gladstone proposes the use of malleable iron bars, of the double T shape, to form almost the only material of the bridge. These bars are to be either rivetted at their flanges, or fastened together by nuts and screws. All the bars are to be placed horizontally; and, at spots where additional strength is required, such as near the abutments or piers, they might be rivetted side by side, so as to form a solid mass; while near the centre of the water way or arch they might be so extended as to form an open iron-work of elegant character. The engineer who suggests this plan points out four advantages which he thinks would accompany its adoption—it would enable a span of almost any length to be made; it would render a nearly flat roadway practicable; it would give a higher water-way than an arch springing from piers in the usual manner; and it would render the use of expensive centering unnecessary.

The fall of an iron railway bridge over the Dee, at Chester, belonging to the Chester and Holyhead Railway Company, in 1847, has led to many enquiries on the nature of such bridges. Mr. Locke, who has constructed so many bridges of stone, brick, and timber, stated in the evidence which he gave in relation to that catastrophe, that he thinks cast-iron to be wholly unfitted for the construction of bridges for railways, unless under special circumstances.

In 1839 a bridge had to be constructed at Grisoles, over the branch canal of Garonne, in France; and as building stone is scarce in that district, M. Lebrun determined to construct it of *béton* or *concrete*. This he accomplished, and the bridge was finished in 1841. Both the French *béton* and the English *concrete* are formed of lime, sand, and pebbles; but there are slight differences in the mode of preparation. The *béton* was laid on course after course; and only as much was made each day as could be laid on in that day. The entire mass of the abutments, and the greater part of the arch, was made of béton: bricks being used only in a few places, to increase the strength.

Mr. Remington's *ærial bridge*, familiar to the visitors at the Surrey Zoological Gardens, has obtained its name from its extreme lightness. It is entirely formed of thin pieces of wood: so thin and light as to excite general surprise that it should be able to bear the weight of many persons at one time. In 1848 Earl Talbot caused a bridge to be built on this system by Mr. Remington, over the river Trent, as part of an accommodation road on the earl's estate near Ingestre. The bridge is 150 feet span; and yet, remarkable to observe, the beams or stringers, six in number, which extend from end to end, are only five inches square at each end, and diminish to 2¼ inches square at the centre of the bridge; they are formed of pieces of timber, 20 to 25 feet long, scarped together at the ends. They rest, at either shore, on a light abutment formed of posts of oak, 6 inches square, framed together with iron clasps. The stringers hang into a slight curve, depressed about two feet in the centre; and the extreme lightness at the centre prevents the structure from being borne down by its own weight. The planks which form the bridge are placed crosswise upon the stringers. The bridge, although strong enough to bear a carriage and horses, cost only 200*l.*; and the timber of which it is formed was growing on the earl's estate six weeks before the completion of the bridge. A similar bridge has been since thrown over the lake in Birkenhead Park, and others have been built in Birmingham and elsewhere.

BRIDGEWATER. Much of the foreign and coasting trade of Somersetshire centres at Bridgewater, which lies nearly at the mouth of the river Parret. The principal imports are grain, coals, tallow, and timber. Coals are imported from Wales, and conveyed into the interior of the country by means of the river Parret and a canal. The foreign trade is principally with Russia, the United States, Canada, Newfoundland, and the West Indies. More than 4,000 vessels, large and small, enter and clear at Bridgewater in the course of a year.

A manufacture peculiar to, and constituting the staple trade of Bridgewater, is the fabrication of that kind of white brick known as *Bath Brick*, so largely used in knife-cleaning; this branch of industry gives employment to many of the inhabitants. These bricks are formed of the sediment or sand of the river Parret, cast into moulds and dried. These

Bath (or more justly Bridgewater) bricks will have the honour of a place in the grand display of 1851; for it is quite fitting that the staple manufacture of a town, however apparently humble, should be there represented. Various manufactures in clay and brick will also be exhibited from Bridgewater.

BRIDGEWATER, FRANCIS EGERTON, DUKE OF, is indissolubly associated with the history of canal engineering in this country. One of the estates which he inherited, situated at Worsley, near Manchester, contained a rich bed of coal; but was comparatively of little value, in consequence of the heavy expense of land carriage and the inadequate means of communication afforded by the Irwell; and this led him to conceive the plan of a navigable canal, for which, in 1758-9, he obtained an act of parliament. From this circumstance he is frequently styled 'the Father of British Inland Navigation.' He chose BRINDLEY for his engineer, and on his plans, and under his superintendence, the work was completed in spite of many difficulties. The length of the main line is above 27 miles, all on the same level, which has rendered great embankments necessary, as the canal crosses several depressions. One of these embankments is 900 yards long, 17 feet high, and 112 feet wide at the base. With the exception of that part between Worsley and Leigh, every part of the canal was executed, under the direction of Brindley, in about five years.

The Duke of Bridgewater died March 8, 1803, without children, and his great wealth was distributed among the collateral branches of his family. The canal property, with the Lancashire, Cheshire, and Brackley estates, he left to his nephew, the late Duke of Sutherland. They are now in the possession of the Earl of Ellesmere.

BRIDPORT is one of the few commercial towns in Dorsetshire; having a safe and busy harbour. It once had a considerable coasting trade in coal and grain; but this trade has been almost entirely lost in consequence of the superior facilities for transmission of goods afforded by railways. Hemp, flax, tallow, timber, and wheat are imported from Russia and the Baltic; and timber from Norway and America. Wines, spirits, skins, coals, culm, and slates are also imported. The exports consist chiefly of the manufactures of the town, and of cheese and butter for which the neighbourhood is celebrated. The manufactures of Bridport are principally of twine, shoe-thread, cordage, sailcloth, and fishing nets. The antiquity of the hemp trade in Bridport has long since dignified a halter with the name of a 'Bridport dagger.'

The townsmen of Bridport very properly intend to illustrate the industry, which has given them their manufacturing title, at the forthcoming exhibition. Specimens of hemp and flax twine, netting, yarn, canvas, girth, webbing, bags, and sacking—for all of which Bridport has been noted ever since the time of Henry VIII—are to be exhibited.

BRIMSTONE. [SULPHUR.]

BRINDLEY, JAMES, shared with the Duke of Bridgewater in the honour of introducing canal navigation into this country. He was born in 1716, and was apprenticed in his 17th year to a millwright near Macclesfield. When the period of his apprenticeship had expired, Brindley engaged in business on his own account; but he did not confine himself to the making of mill machinery. His reputation as a man of skill and ingenuity steadily increased; in 1755 he executed the machinery for a silk-mill at Congleton; and in 1756 he erected a steam-engine at Newcastle-under-Lyne.

Shortly after this time, Brindley was consulted by the Duke of Bridgewater on the practicability of constructing a canal from Worsley to Manchester. His success in this undertaking was the means of fully awakening public attention to the advantages of canals. Within forty-two years after the Duke's canal was opened, application had been made to Parliament for 165 acts for cutting canals in Great Britain, at an expense of above thirteen millions. In 1766 the Trent and Mersey Canal was commenced under Brindley's superintendence. It is 93 miles long, and unites the navigation of the Mersey with that of the Trent and the Humber. It was called by Brindley the 'Grand Trunk Navigation,' owing to the probability, from its great commercial importance, of many other canals being made to join it. Brindley next designed a canal 46 miles in length, called the Staffordshire and Worcestershire Canal, for the purpose of connecting the Grand Trunk with the Severn. He also planned the Coventry Canal, but did not superintend its execution. He, however, superintended the execution of the Oxford Canal. The canal from the Trent at Stockwith to Chesterfield, 46 miles long, was Brindley's last public undertaking. He also surveyed and gave his opinion on many other lines for navigable canals besides those mentioned. Brindley died in 1772, aged 56.

BRISTOL. This famous old city has been an emporium of commerce for a longer period than almost any other sea-port in the kingdom. It long preceded its great rival Liverpool, which has now so signally overtaken it. The commercial buildings of Bristol are mostly connected more or less closely with the docks. These docks were formed by excavating a new course for the Avon south of the city, and converting the whole of the old channel, through the city, into one floating harbour, about 3 miles in length. By subsequent changes and enlargements, the harbour and docks have gradually been made capable of accommodating a large amount of shipping. The dock rates on vessels and goods, until 1848, far exceeded the corresponding rates at the ports of London, Liverpool, Hull, and Gloucester; but a gradual decline in the commerce of Bristol has led the inhabitants generally to see the necessity of modifying the port charges, in order to invite shipping to bring their cargoes thither.

By a special Act obtained in 1848 the docks are transferred from a private company to the corporation; and new dock charges have been established, much more calculated to attract shipping to the port. On November 13, 1848, a grand procession paraded through Bristol to commemorate this important alteration. It has been found that arrivals and departures of shipping have considerably increased since the new system was adopted. There were in 1849 about 300 vessels registered at the port, some of very large tonnage. The tonnage of merchandize brought into Bristol is always much greater than that shipped from thence; on account of Bristol being one of the chief places of import of West India produce.

The foreign trade of Bristol principally consists in imports of sugar, rum, wine, brandy, colonial and Baltic timber, tallow, hemp, turpentine, barilla, dye-woods, fruits, wheat, and tea. The principal articles of export are iron, tin, bricks, refined sugar, glass bottles, Irish linen, and manufactured goods. Bristol derives a considerable portion of her supply of foreign produce coastwise under bond principally from London and Liverpool, but also from the minor ports of Gloucester, Newport, Bridgewater, Exeter, Barnstable, and Bideford. The coasting trade is very considerable, particularly with Ireland. The imports principally consist of iron, tin, coal, salt, Irish linens, and agricultural produce; the exports of articles of foreign and colonial produce, particularly groceries, tea, wines, and spirits, and of the manufactures of the place. The quantity of live stock imported into Bristol from Ireland in three successive years was as follows:—

	Pigs.	Sheep.	Cattle.	Horses.
1845	32,926	1,603	1,015	38
1846	46,811	3,590	4,925	19
1847	33,673	46,465	13,602	381

The existing manufactures of Bristol are glass bottles, crown and flint glass, brass wire, pins, sheet lead, zinc, spelter, chain cables, anchors, machinery, drugs, colours, dyes, painted floor cloth, earthenware, refined sugar, starch, soap, British spirits, tin, copper and brass wares, bricks, beer, porter, pipes, tobacco, and hats. Most of these manufactures are either carried on within the city or in its immediate neighbourhood; but the manufacturing circuit may be considered to extend 6 miles around. The principal factories are those for glass, sugar, iron, brass, floor-cloth, and earthenware. In addition to these there has been established a very large joint-stock cotton factory in the parish of St. Philip, under the title of the Great Western Cotton Works. The building was commenced in 1837. It consists of an immense range of spinning, weaving, bleaching, and repairing shops, with all the appliances for employing 2000 hands. In May, 1850, this building suffered extensively by an accidental fire.

As a specimen of engineering work we must not omit mention of the suspension bridge over the Avon. The original act for the construction of the bridge was obtained so far back as 1831; but as it appeared likely to be a failure from the exhaustion of the funds, four subsequent acts have been obtained for permitting the postponement of the works. The last of these postponing acts was passed in 1848, by which the powers of the Bridge Company are extended to 1853. A sum of 45,000*l.* has been collected, partly by the accumulation at compound interest of a sum of money left for this purpose in 1754, and partly by private subscription; and this sum has been expended in erecting the abutments and piers on both sides of the river, the excavation of the rock for the roads of approach, and the purchase of a portion of the iron-work. The estimate for the future cost is 30,000*l.*, towards which there is nothing forthcoming; but it is said that there are negociations now on foot which will render the finishing of this remarkable bridge a probability. [Suspension Bridge.]

Among the contributions from Bristol to the Industrial Exhibition will be one of a peculiarly interesting character; viz., a few specimens of native African manufacture, consigned by the black king of Dahomey to the care of Messrs. King, African merchants at Bristol. Nothing can better show how widely spread is the fame of this Exhibition.

BRISTLES. The bristles so largely used in brush making are brought almost entirely from Russia. The importation in 1849 exceeded 2,000,000 lbs.

BRITANNIA BRIDGE. The two splendid

works over the Menai, by Telford and Stephenson, will be best described in conjunction. [MENAI BRIDGES.]

BRITISH AMERICA. The commercial and industrial features of this vast country are noticed under the names of the territories which compose it [CANADA; NOVA SCOTIA; &c.] We may here briefly state that the British produce and manufactures, exported to the whole of those colonies in 1849, amounted in value to 2,279,193*l*.

BRITISH ASSOCIATION. Those who appreciate the intimate connexion between theory and practice, will be ready to expect that an Association 'for the advancement of science,' ought to advance industrial art likewise. This has been most undeniably the case in respect to the distinguished body here under notice. From the first meeting in 1831 to the twentieth meeting in 1850, every year has contributed something to the improvement of manufacturing industry through its medium. Mr. Eaton Hodgkinson's researches on the strength of iron and other materials; Mr. Scott Russell's very remarkable investigations on waves, and on the best form of ships to accommodate themselves to the waves; the long and patient observations of Dr. Whewell and Mr. Burt on tides; Baron Liebig's labours in the fruitful field of organic chemistry—such are a few among the numerous services, fostered by the Association, which have been found to be directly beneficial to some among the many departments of art. And the British Association has shown, too, that Art can aid Science, as Science can aid Art; for many beautiful pieces of mechanism have been brought forward under the auspices of the Association, which have rendered important services to scientific investigations.

BRITISH MUSEUM. This valuable establishment so instructively illustrates Art—fine art in respect to its best specimens, and industrial art in respect to its minerals, &c., that we must not pass it over without a few words of notice. The establishment of a national Museum was suggested by the will of Sir Hans Sloane, who, during a long period of eminent practice in physic, had accumulated, in addition to a numerous library of books and MSS., a large collection of objects of natural history and works of art; these he directed should be offered after his death, which took place in 1753, to the British Parliament for the sum of 20,000*l*., the collection having cost him 50,000*l*. From that period to the present, valuable donations of books, manuscripts, sculptures, bronzes, coins, prints, minerals, &c., have been made; and Parliament has appropriated large annual sums to the same object. Hence has gradually accumulated the present most valuable collection.

The buildings forming the New British Museum are arranged in a hollow square, facing the cardinal points of the compass. The southern or Russell-street front is the principal one, and presents to view a columnar façade of the Ionic order. At the extreme west end is a detached building, and another one at the east end; these are dwelling-houses and offices for the librarians and chief officers of the establishment.

There are two stories of galleries and rooms round the greater part of the building, to some of which the general public are not admitted. All the ground-floor between the portico-entrance and the south-east angle is occupied as a depository for manuscripts, and as apartments for receiving, sorting, and reading manuscripts. The ground-floor of the greater part of the east side is occupied by the King's Library, a magnificent apartment, 300 feet long. The entire ground-floor of the north side is closed from general visitors, being devoted to literature and study; there are two large reading-rooms, together about 120 feet in length, and a library for books, extending 200 feet. At the north-west angle of the building, and in one or two other parts, are collections which are not thrown open to the public generally; such as the prints, the botanical collection, the coins, and the gems.

The door in the centre of the portico gives entrance to the new hall or vestibule. This is a fine large apartment, worthy of the building to which it gives access. On the right are the two statues of Sir Joseph Banks and Shakspere, on each side of the door leading to the manuscript department; and on the left is the statue of the Hon. Mrs. Damer, the lady sculptor, who left the attractions and fascinations of gay life for the mallet and chisel. In front is a glazed door opening to the central quadrangle, the buildings on three sides of which can be well seen from this point; and at present, until other arrangements are completed, the extraordinary Lion and Bull brought by Mr. Layard from Nineveh are placed near this door. The hall is lofty, and the ceiling is richly painted in encaustic colours, formed into square compartments of divers tints. On the left, close to the front wall of the building, is a passage leading to the various sculpture galleries; and northward of this is the grand staircase, a noble feature of the building. The ascent of nearly seventy stone stairs, half of them westward and then the other half eastward, the elegant balustrade, and the encaustic work of the ceiling, come with freshness and welcome upon the eyes of those who for many years have been accustomed to the dingy entrances to the Museum.

Arrived at the top of the stairs, a range of rooms extends eastward along the building. By the side of the upper part of the staircase, over the passage leading to the sculptures, is an antiquarian or ethnographical room, in which the dresses and ornaments, the industry and implements, of all nations, are illustrated in a highly interesting manner. The room at the head of the stairs, and immediately over the entrance-hall, is devoted to zoology. Beyond this room, towards the east, are two others, devoted like it to zoological specimens. The Mammalia Saloon forms the upper story of the south-east angle of the Museum; and from thence proceed a magnificent suite of rooms, called the Eastern Zoological Gallery, extending along the whole eastern side of the building from south to north, and filled with specimens illustrating the natural history of animals. Arrived at the north-east angle of the building, we find a double range of galleries almost as beautiful as the former: they are side by side, and occupy the upper floor of the whole northern side of the Museum, from end to end. One of these ranges is the Northern Zoological Gallery, and the other the Mineralogical Gallery.

At the north-west angle is a staircase leading down to the lower story; but turning to the left, a range of rooms leading along the west side of the building is devoted to the reception of Egyptian and Etruscan antiquities. There are portions of this west side lately opened to visitors, but not yet filled with specimens: they lead to the western entrance of the Ethnographical Room; so that the entire circuit of the building may now be made. The staircase conducts the visitor down to an ante-room at the northern extremity of the great Egyptian gallery; from which ante-room proceeds an entrance to another smaller Egyptian room, and also doors leading to the library not open to the public. Traversing the Egyptian Gallery southward, we come to a kind of large central saloon; westward, and projecting from this range, is the Phigaleian sculpture-room; and beyond this the Elgin Saloon, where the valuable sculptures from the Parthenon are placed.

All the rooms from the Egyptian Saloon back to the entrance are of recent construction, and many of them are not yet occupied: they will contain the Townley, the Xanthian, the Nineveh, and other collections of sculptures.

Such is a sketch of the important building which is silently and healthfully educating thousands of persons; for every visit is an educational lesson, in some form or other. Of the 1,062,218 visits made to the British Museum in 1849; of the 19,000 visits made on the 'boxing-day' of 1850; it may safely be said that they were visits in a proper direction, having a germ of good in them.

BRIXHAM. The prosperity of this seaport of Devonshire is chiefly dependent on its fishery, which is said to be the largest in England. More than 200 sail of vessels, comprising 20,000 tons of shipping, and employing 1,500 seamen, belong to this town, most of which are engaged in the fishing trade. The average amount received for fish is said to be 600*l.* per week. The best of the fish are sent to Exeter, Bath, Bristol, and London. The cost for carriage alone has been calculated to average 1000*l.* per annum. Turbot, soles, whiting, plaice, mullet, mackerel, and other kinds of fish are taken in considerable numbers. During the London season about 50 of the decked trawl boats are usually absent from Brixham, being employed in supplying the London market with soles, turbots, &c., from Hull and Ramsgate, fishing over all the intermediate space between those places. Several of the vessels belonging to Brixham are employed in the Mediterranean, Spanish, and coasting trade.

BROKER. In relation to ordinary commercial dealings, a broker is a person employed in the negotiation of mercantile transactions between other parties, and generally engaged in the interest of one of the principals, either the buyer or the seller, but sometimes acting as the agent of both. As it usually happens that brokers apply themselves to negotiations for the purchase and sale of some particular article or articles, they acquire an intimate knowledge of the qualities and market value of the goods in which they deal, and obtain an acquaintance with the sellers and buyers as well as with the state of supply and demand, and are thus enabled to bring the dealers together, and to negotiate between them on equitable terms. There are separate brokers in London for nearly all the great articles of consumption; and there are also ship-brokers, exchange-brokers, stock-brokers, share-brokers, &c., to conduct the transactions indicated by their names. Custom-house brokers, or agents, are licensed by the Commissioner of Customs; and no person without such licence can transact business at the Custom-house or in the port of London relative to the entrance or clearance of ships, &c.

BROMINE, an elementary fluid body, was discovered in 1826 by M. Balard, and named from *βρῶμος* (stink), on account of its strong and disagreeable odour. It is found in sea water, in salt springs, in mineral waters, in many marine plants, and in some marine animals. Balard first procured it from a salt spring; but it is now obtained from various sources.

Bromine is liquid at the usual temperature of the air. Its specific gravity is 2.996. It is poisonous. In considerable bulk its colour is a deep brownish red; in small quantities it is of a hyacinthine red. Its odour is extremely strong, greatly resembling that of chlorine; its taste is disagreeable. When exposed to a temperature between zero and 4° of Fahrenheit, it becomes solid, crystalline, brittle, and hard enough to be powdered. It boils at about 116° Fahrenheit, and its volatility is great. It suffers no change by the agency of light, heat, or electricity, and, having never been decomposed, it is regarded as an elementary or simple substance. It is very corrosive.

The various combinations of bromine with other substances have been hitherto but little used in the arts.

BROMSGROVE. In this Worcestershire town the linen manufacture was formerly carried on to a considerable extent, but has been entirely abandoned. Nail-making is now the principal trade, but there is also an extensive manufactory for patent buttons.

In the parish of Stoke Prior, and closely adjoining that of Bromsgrove, are situated the extensive salt and alkali works of the British Alkali Company. The manufacture of salt has been carried on for centuries in the adjoining borough of Droitwich, where it is prepared from rich springs of native brine. The only situations where rock-salt had been met with in this island were in Cheshire, previously to its being discovered at Stoke Prior, where it was obtained in 1829, in the course of sinking a pit in search of brine. The beds of salt were of great thickness, and were excavated to a considerable extent; but at present the supplies for making refined salt are derived from a natural brine spring, which has communicated with the excavations. Immediately after making this discovery, the proprietors erected extensive works for the manufacture of salt, and for the preparation of British alkali, by the decomposition of this substance, which very speedily changed the green fields and retired lanes into an active manufactory and a lively village. The works have become very extensive and the centre of a considerable population.

BROMWICH, WEST, or West Bromwich, in Staffordshire, affords a remarkable instance of the growth of population and wealth through mining and manufacturing industry. A few years ago it was little else than a barren heath lying on either side of the road from Birmingham to Wolverhampton; but it has gradually grown up to a town nearly three miles in length, which takes the name of the parish in which it is situated. The existence of iron and coal beneath the surface of the whole parish is the cause of the growth of the town. The manufacture of iron goods is carried on to an immense extent at Bromwich: guns, gun-locks, swords, bayonets, saddlers' ironmongery, fire-irons, coach ironmongery, chains, bolts, nails, and agricultural implements, are among the kinds of iron goods made here.

BRONZE is essentially a compound of copper and tin, which metals appear to have been among the earliest known. Copper is not unfrequently found in its metallic state, and fit for immediate use; and tin, though not so met with, often occurs near the surface, and its ore is easily reduced. These metals, though neither of them possesses the hardness requisite for making instruments either for domestic or warlike purposes, appear to have been early found capable of hardening each other by combination; the bronze, which is the result of this combination, consisting of different proportions of them, according to the purposes to which it is to be applied.

Bronze is always harder and more fusible than copper; it is highly malleable when it contains 85 to 90 per cent. of copper; tempering increases its malleability; it oxidises very slowly even in moist air, and hence its application to so many purposes. The density of bronze is always greater than that of the mean of the metals which compose it: for example, an alloy of 100 parts of copper and 12 parts of tin is of specific gravity 8.80, whereas by calculation it would be only 8.63.

The green hue that distinguishes ancient bronzes is acquired by oxidation and the combination with carbonic acid; and the moderns, to imitate the effect of the finer antique works, sometimes advance that process by artificial means, usually by washing the surface with an acid. Vasari alludes to this practice among the artists of his time, and to the means they adopted to produce a brown, a black, or a green colour in their bronze.

Bronze was well known to the ancients. Among the remains of bronze works of art found in Egypt none are of large dimensions. Many specimens of bronze works found in India are doubtless very ancient. In the time of Homer, arms, offensive and defensive, are always described as being made of bronze, or perhaps copper alone, which it is possible they had some means of tempering and hardening. The art of casting statues seems to have been first practised in Asia Minor, Greece, properly so called, being then probably too uncivilised to undertake such works. The first and most simple process, among the Greeks, appears to have been *hammer-work;* in which lumps of the material were beaten into the proposed form; and, when the work was too large to be made of one piece, several were shaped, and the different parts fitted and fastened together by means of pins or keys.

The art of metal-casting in regular moulds was undoubtedly known very early, though its adoption in European Greece is probably of a comparatively late date. Its progress was evidently marked by three distinct stages. The first was beating out the metal, either as solid hammer-work or in plates. The next was casting it into a mould or form, the statue being of course made solid. The last stage was casting it into a mould, with a centre or core to limit the thickness of the metal. Bronze-casting seems to have reached its perfection in Greece about the time of Alexander the Great. The ancient statuaries seem to have been extremely choice in their selection and composition of bronze; and they seem also to have had a method of running or welding various metals together, by which they were enabled to produce more or less the effect of natural colour. Some works are described that were remarkable for the success which attended this curious and, to us, unattainable process. They also tinted or painted their bronze with the same view of more closely imitating nature. Pliny states that there were three sorts of the Corinthian bronze; the first, called candidum, received its name from the effect of silver which was mixed with the copper; the second had a greater proportion of gold; the third was composed of equal quantities of the different metals.

The Romans never attained any great eminence in the arts of design. Their earliest statues were executed for them by Etruscan artists. Rome, however, was afterwards filled with a prodigious number of works of the best schools of Greece; and artists of that country, unable to meet with employment at home, settled at Rome. Zenodorus executed some magnificent works in the time of Nero. But Pliny, who lived in the reign of Vespasian, laments the decline of the art, and the want of skill of the artists, in his time. The practice of gilding bronze statues does not seem to have prevailed till taste had much deteriorated. The practice of art among the Romans declining rapidly, and with but few interruptions, ceases to interest us about A.D. 200. In the beginning of the thirteenth century, at the taking of Constantinople, we read that some of the finest works of the ancient masters were destroyed for the mere value of the metal. Among the few works saved are the celebrated bronze horses, which now decorate the exterior of the church of St. Mark at Venice.

Passing over the intermediate age of barbarism, we arrive at the epoch of the revival of art in Italy, under the Pisani and others, about the fourteenth and fifteenth centuries. The celebrated bronze gates of the Baptistery at Florence, by Ghiberti, which M. Angelo said were fit to be the gates of Paradise, are among the more remarkable works of the time. In the succeeding century we find Guglielmo della Porta practising the art with great success; and he is distinguished by Vasari for adopting a mode of casting that was considered quite original, in executing his colossal statue of Paul III. The metal when run from the furnace, was carried downwards by a duct, and then admitted to the under side or bottom of the mould, and thus, acted upon by a superior pressure, as in a common fountain, was forced upwards till the mould was entirely filled. It is necessary in this process that the mould should be kept in a state of great heat, in order that the metal may not cool before the whole is run. But among the artists who are celebrated for their skill in bronze-casting, Benvenuto Cellini holds a distinguished rank: there are few collections that cannot boast some specimens of his smaller productions, while the larger works that remain, particularly at Florence, prove that his high reputation was not undeserved. In his process the metal was allowed to flow at once from the furnace into the channels or ducts of the moulds.

The modern practice of the English, French, Italian, and German artists does not differ materially in its principle, from that of the earlier Italians. The process is described under FOUNDING.

Bronze for cannon in England is composed of 90 copper and 10 tin. Bronze for cymbals and tamtans is composed of 78 copper and 22 tin; in France, of 100 copper and 11 tin. English bell-metal consists of copper 80, tin 10.1, zinc 5.6, lead 4.3, = 100. Reflectors for telescopes consist of 66 parts of copper and 33 parts of tin; they resemble steel in colour, are very hard and brittle, and susceptible of a fine polish. Bronze for medals is formed of 100 copper, and 7 to 11 of tin and zinc.

At the Mediæval Exhibition of 1850, there were many bronzes of great beauty displayed. Vases, chains, keys, fibulæ, lamps, busts, statuettes, censers, fountains, inkstands, ewers, —these were among the specimens exhibited.

The articles of bronze imported are classed by the customs' authorities under three groups —1st. works of art, 2nd. other articles in bronze, and 3rd. bronze powder: the first group is stated at from 200 to 300 cwts. annually; the second and third groups have a value of about 2000*l.* annually.

BRONZING; BRONZE POWDER. Much ingenuity is displayed in imitating the colour of ancient bronzes—both the greenish and the rich golden tints. Metals, wood, and plaster, are all subject to surface-processes having this object in view.

Captain Pidding states that the Chinese exercise the art of bronzing in a very superior manner. After having rubbed the vase or other ornament with coal-ashes and vinegar, they dry it in the sun, and then coat it with a composition of which the following are the ingredients—two parts of verdigris, two of cinnabar, two of sal ammoniac, two of the beak and liver of duck, and five of pounded alum, —moistened to the consistency of a paste. When the article is thus prepared, it is passed through the fire, and washed when cold; again it is coated with the composition, again fired, and again washed; and so on for several times in succession.

Becquerel introduced to the notice of the Académie des Sciences, a few years ago, a method of bronzing, in which a thin layer of bronze is applied to the surface of any article of iron, steel, lead, zinc, tin, or other metal. It is effected by precipitation from a solution, through the agency of a galvanic battery in the usual manner of electro-metallurgy; but the difficulty surmounted consists in the discovery of a proper solution. The solution described by Becquerel consists of carbonate of potash, chloride of copper, sulphate of zinc, and nitrate of ammonia; with a plate of brass or bronze as a positive decomposing plate.

A process of bronzing on paper is now frequently adopted for ornamental purposes. Thin plates of copper, or of copper alloyed with some other metal, are beaten out into thin leaves, and these leaves are ground or worked to powder. A pattern is printed on the surface of paper with an adhesive and rapidly-drying varnish; and just before this varnish is dry, the bronze powder is rubbed on with a piece of soft cotton, whereby a metallic lustre is produced, varying in its tint from a bright gold to a deep red colour, according to the metallic constituents of the bronze powder. Sheets of paper, thus bronzed after having been glazed and printed,in various colours, now form the highly adorned coverings for albums and many other kinds of books.

BRU'CIA, a vegetable alkali, found in the bark of the *strychnos nux vomica*, and in some other kinds of bark. It is a non-crystallised substance, resembling wax in appearance; but it crystallises under certain circumstances in colourless oblique four-sided prisms. It combines with the principal acids to form *Nitrate*, *Muriate*, *Sulphate*, *Oxalate*, *Phosphate*, and *Acetate of Brucia:* most of which are crystallised, and have a bitter taste.

Brucia acts on the human system as a violent poison, and in precisely the same manner as strychnia, but more gently, being much less powerful.

BRUGES (*Brugge*), capital of the Belgian province of West Flanders, has considerable manufactures of linens, lace, woollen and cotton goods, salt, refined sugar, earthenware, paper, distilled liquors, and other minor branches of industry.

Many of the Bruges manufactures will be illustrated at the Exhibition of 1851.

BRUNEL, MARK ISAMBERT. So long as engineering genius and mechanical invention are honoured, so long will the name of Brunel occupy a niche among the worthies of industry.

The late Sir M. I. Brunel was born at Hacqueville in Normandy, in 1768. He studied first for the church, and then for the navy; but the natural bent of his mind marked out another career for him. He was obliged to flee to the United States during the French Revolution, and here he commenced his engineering career; but feeling that England was a better sphere for him, he crossed the Atlantic about the year 1800, and devoted the rest of his life to mechanism and engineering in the country of his adoption. His first great work was the Block Machinery at Portsmouth, which occupied him till 1806. [Block Machinery.] He next constructed the Royal Saw Mills at Chatham and Woolwich. Soon after this he invented a beautiful little machine for winding cotton thread into balls. In 1813 he contrived an extensive series of machines for making shoes for the army; but these machines have not been used since the war. He was engaged in building one of the early steamboats, and introduced many improvements in marine engines. After numerous minor works he projected the Thames Tunnel: having previously proposed to the Emperor Alexander the construction of a tunnel under the Neva at St. Petersburg, to obviate the evils occasioned by the freezing of the river in winter. The Thames Tunnel was commenced in 1824, but was not finished (so far even as it may yet be deemed finished) until 1843, under an amount of difficulty which would have crushed any but an indomitable mind. [THAMES TUNNEL.]

During the later years of his life, Sir Mark (who received the honour of knighthood during the Melbourne administration) did not engage in any great enterprizes, but lived quietly and respected to a good old age. He died in Dec. 1849; leaving a worthy successor in his son, the present Mr. I. K. Brunel, engineer of the Great Western Railway and of other extensive works.

BRUNN, the capital of the Austrian province of Moravia and Silesia, is the principal seat of the woollen manufactures of Austria. Its fine woollen cloths and kerseymeres are in great repute. It also manufactures largely silks, ribbons, yarns, machinery, leather, cotton prints, soap, and vinegar. It has four wholesale markets in the year, which are each of fourteen days' duration, and to which manufacturers from all parts of Austria resort in considerable numbers.

BRUNSWICK. The duchy of Brunswick is rich in mines, which are of two classes; one class comprising such as are worked in conjunction with the Hanoverian government, and the other independently of it. The annual produce of the first class, which includes the mines on the Rammelsberge, in the Upper Harz, has ever since the year 1788 been divided into seven shares, of which Hanover takes four and Brunswick three. These mines are under the direction of a joint board at Goslar, and consist of one of gold, three of silver, copper, and lead, and three copper and sulphur works. The independent mines lie on the Lower Harz, in the principality of Blankenburg, near Seesen, and the district of the Weser; their principal produce is iron.

Brunswick produces marble, alabaster, limestone, gypsum, potter's clay, asbestos, serpentine-stone, agate, jasper, chalcedony, garnets, porphyry, sandstone, freestone, coal, and alum. There are salt-works at Salzdahlum, Schöningen, Salzliebenhall, and Juliushall.

The chief manufactures of the Duchy are metals, yarn and linen, stockings, cloth made of a mixture of woollen and linen, oil, paper, gypsum, earthenware, tobacco pipes, glass, soap, and beer. The export and import trade is small, on account of the want of sea-coasts.

BRUSA or BRUSSA, a city in Asia Minor, about 60 miles from Constantinople, is one of the most flourishing towns in the Turkish empire. Its satins and tapestry are of the best quality. Gauzes, taffetas, and cottons, are also manufactured. The trade with the interior is carried on by the caravans which pass through the town between Constantinople and Smyrna. Brusa is the centre of a district in which a great quantity of raw silk is produced, to the amount of about half a million lbs. annually; and the cultivation of the mulberry is yearly on the increase. Grapes, melons, and fruits of all kinds, are abundant. Meerschaum clay is dug in the neighbouring mountain. British long-cloths, dyed sarcenets, cotton shirtings, cambrics, *chalès* or thin figured woollen dresses, cotton twist, Paisley shawls, and printed calicoes, find a ready market at Brusa.

BRUSH-MAKING. Brushes and brooms may be classified into simple brushes, or such as consist of a single tuft of hairs, be it large or small; and compound brushes, or such as have many tufts. The former may be subdivided into such as are inserted in a handle, or in a tube which serves to connect them with a handle, as the several varieties of *hair pencils*, mounted in quills, and painters' *tools*, which are similarly inserted in tubes or flattened cases of tin, or put into the cleft end of a wooden handle, and bound round with twine or thread, smeared over with glue; and the larger and coarser brushes, in which the end of the handle is inserted and bound up in the midst of the tuft, such as the large painting and dusting *brushes* (technically so called), used by house-painters, and the much larger *carpet brooms* and *besoms* or *birch-brooms*. *Stock-brushes* form an intermediate kind, in which several simple tufts or brushes are separately attached, side by side, to the thin edge of a flat board-like stock or handle: such are used for whitewash and distemper. Compound brushes, consisting of several tufts or *knots*, inserted in a stock or handle, range under two principal kinds: *set-work* or *pan-work*, and *drawn work*. For both the wooden stock is bored, usually in a lathe, with holes varying in size, depth, and direction, according to the kind of brush. In *pan-work*, the tufts or knots are formed by gathering together as many bristles or hairs as may be needed, striking one end even, dipping it in melted pitch, binding it round with thread, and, having dipped it again in the pitch, *setting* it in one of the holes in the stock with a peculiar twisting motion. Common house-brooms of most kinds, and some *dusters*, are made in this way. In *drawn* brushes the boring of the stock is more carefully performed, and a small hole is carried through from the extremity of each knot-hole to the back of the stock; and the brushmaker, taking in one hand about half as many bristles as will fill the knot-hole, passes their root ends through the bight or loop of a fine flexible wire which, with the other hand, he has passed double through the hole from the back of the stock. He then pulls the wire smartly, the effect of which is to draw the tuft into a bight or double, and to force it as far as possible into the knot-hole. After proceeding thus from hole to hole, he cuts the ends of the bristles evenly to the required length with shears. Brushes of this character comprise scrubbing, shoe, clothes, tooth, and nail brushes. In such the stiffness of the root end of the bristles is mostly desirable; while in such as are used for laying on colour, dusting, or sweeping, the softness of the *flag* or taper ends, which are cut as little as possible, is preferable. The stocks of drawn brushes are usually covered at the back with a veneer, which conceals and protects the wires; but small brushes set in bone or ivory are often drawn with silver wire, which is either left visible or sunk in fine grooves which are subsequently filled with hard red cement. The best are *trepanned*, or have the drawing holes so contrived as to come out, not through the back, but at some unconspicuous part of the stock, where they may be filled up with small plugs after the drawing, which is done with silk instead of wire. Mr. Hancock has patented a brush in which leather is used instead of wood or other unyielding material for the stock.

The brush manufacture is chiefly a domestic one, and is well adapted for the employment of females and children. The chief materials employed are *bristles*, many of which are imported from Russia and Poland, and are sorted into black, gray, yellow, white, and *lillies*, the lightest of all; horse-hair, goat's hair, and other kinds of hair; fibres of whalebone; a dark-coloured vegetable fibre called *bass*, used for stable and other coarse brooms; and *wisk*, a light-coloured vegetable substance of much finer quality, used for carpet-brooms, and a very fine variety for velvet-brushes; woods of various kinds for the stocks and veneers; and wire, usually of brass, but sometimes of a superior compound, looking much like copper, called red brass wire.

Mr. Cole, a brush-manufacturer, took out a patent in 1842 for numerous improvements in brush-making. In the general modes of making brushes the bristles are fixed in their places either by some kind of cement or by wire; but in Mr. Cole's new method the knot of bristles is kept in each hole by the hole being made of a conical shape, with the smaller end of the cone at the face or hair side of the brush: the knot is so shaped that it maintains its place in the brush without either cement or wire. A second improvement consists in steeping in a preservative solution the string with which some brushes are bound round, so as to enable them to be placed in water without loosening. A third consists in a new mode of fastening wedge-shaped handles into various kinds of brushes. A fourth consists in the manufacture of a new kind of brush for delicate purposes, by making a covering of plush to a foundation of white flock. A fifth consists in making brushes or pencils of spun glass, by which aquafortis and other corrosive acids can be applied by silversmiths and jewellers with more delicacy and safety than by any of the usual means. A sixth improvement is in the construction of brushes intended for cleansing decanters and bottles. A seventh relates to brushes for cleaning cruets and small phials.

Various patents have been taken out for making flexible backs to brushes.

A recent project, the subject of a patent, is to make brushes and brooms of the branches of the cabbage-palmetto tree, in such a way that the handle shall form one piece with the brush.

In Mr. Cocker's brushes, registered in 1849, the bristles are set diagonally, by which more of them are brought into action at once, and the surface of the brush is firmer.

BRUSSELS, the capital of Belgium, is a place of considerable manufacturing activity. The manufacture of lace is carried on to a considerable extent; the quality is very superior, and the finest sorts fetch from 3,000 to 4,000 francs a pound. A few facts concerning the lace manufacture of Brussels, in connection with the Exhibition of Industry, are given in the *Introduction* to this work. Many other manufactures are also prosecuted, among which are carpets, silk hats, cutlery and surgical instruments, hosiery, calicoes, gold and silver lace, paper-hangings, upholstery, porcelain, hardware, and chemical products. Vast numbers of books are printed in Brussels, a large number of which are cheap reprints of foreign works, chiefly French.

BRYO'NIA, the wild Bryony of our hedges, *Bryonia dioica*, is a plant formerly much employed in rural pharmacy, but now disused. It was chiefly employed on account of the powerful drastic properties of its root. Overdoses are extremely dangerous, and sometimes even fatal. The peculiar principle of Bryony-root is called *bryonin*. It is a yellowish white substance, sometimes with a red or brownish tint. Its taste is at first rather sweet, then styptic, and extremely bitter. It is a drastic purgative, and poisonous in too large doses.

BUC'CINA, a military instrument of the shrill horn or cornet kind, in use among the ancients, and by some supposed to have been formed of the horn of the bull or goat. According to others it was the shell of the buccinum, a fish. Vegetius says that it was made of brass, and bent in a circle. The probability is, that in its primitive state it was a simple horn, and that subsequently it was formed of a more durable material.

BUCHAREST, the capital of Wallachia, is the grand commercial mart for the principality, and the inhabitants carry on an extensive trade in grain, wool, honey, wax, tallow, and cattle. There are no large manufactures; but small quantities of woollen cloths, carpets, brandy, &c., are made.

BUCK-WHEAT. The cultivetion of buck-wheat has never been very extensive in the variable climate of Britain. It is not so well adapted to cold wet soils as to warm sands; nor is it so certain a crop as oats or barley on lands which are suited to the growth of these grains. For countries where there are very poor light lands with a hot dry climate, unfavourable to the growth of oats and not rich enough for barley, buck-wheat is a great resource. Under particular circumstances, it might be introduced with advantage into many parts of England where it is now unknown. It is sown tolerably thick, and when the plant is in its greatest vigour and in full blossom a roller is passed over the crop to lay it level with the ground. Manure is seldom or never laid upon land in which buck-wheat is sown, because even where manure is abundant it is reserved for other crops supposed to require it more.

Buck-wheat is sometimes cut in its tender state for soiling cattle. It is said to increase the milk of cows, and is occasionally pastured by sheep. It may be given to horses instead of oats, or mixed with them. No grain seems so eagerly eaten by poultry, or makes them lay eggs so soon and so abundantly. The meal, when it is ground, is excellent for fattening cattle or pigs. The flour is fine and white, but, from a deficiency in gluten, does not make good fermented bread. It serves well however for pastry and cakes; crumpets made of buck-wheat flour, eaten with butter, are a favourite dainty with children in Holland. A hasty pudding is also made of the flour, with water or milk, and eaten with butter or sugar.

Out of nearly 11,000,000 quarters of corn and meal imported in 1849, only 627 quarters were buck-wheat.

BUCKINGHAMSHIRE. A little cheese is made in this county; but the quantity of butter is much larger. It is chiefly sent to London made up in the form of oblong rolls weighing two pounds each. It is sent in baskets called from their shape *flats*, which hold from 20 to 40 rolls. Their depth is uniformly 11 inches. Each flat is marked with the initials of the dairyman who sends the butter, and the carrier who conveys it, to whom also the flat belongs. Many of the calves in the dairy farms are fattened for veal, for the London market. The rearing and fattening of ducks for the early London season is carried on to a large extent. It is said that ducks to the value of 4,000*l* are sent annually from Aylesbury alone, and 20,000*l*. worth from the whole county.

BUDA, or OFEN, is that half of the metropolis of Hungary which stands on the left bank of the Danube; the other half, Pesth, being on the right bank. Buda manufactures a little silk and velvet, leather, some cottons, and woollens. It possesses also a cannon-foundry, copper foundries, a gunpowder manufactory, a silk-spinning mill, and a tobacco manufactory. The trade of the town principally consists in the wines produced by the vineyards in the environs, to the annual amount of about 4,500,000 gallons. This wine, which is well known under the name of 'Ofener-wein,' comes from the extensive vineyards belonging to the town itself, which are said to cover an area of 70 square miles. But Buda is now perhaps more interesting to us since the magnificent suspension-bridge over the Danube has been built by our countryman, Mr. Tierney Clark: perhaps the finest engineering work on the Danube.

BUDDING is an operation in horticulture, by means of which the branches of one kind of plant are often made to grow upon the stem of another kind. It is adopted for the purpose of artificial propagation, either by planting the separate buds in earth, or by introducing them into the branches of other plants. The former is called propagation by eyes; the latter only is technically named budding.

There are several modes of budding, such as *reversed budding* and *scallop-budding*, which are occasionally practised. Roses, plums, peaches, nectarines, cherries, and many other plants are chiefly propagated thus, and there is no theoretical reason why it should not be extended to all species. In practice however it is occasionally found impracticable, as in heaths, in vines, &c., owing to specific causes which vary in different instances.

Budding is usually performed in the months of July and August, because at that season the bark separates freely from the wood, and the young buds are fully formed; but, whenever the two latter conditions can be satisfied, the operation may take place equally well.

BUDE-LIGHT is the name given by its

inventor Mr. Gurney to a vivid flame, employed in lighting churches and other buildings. Originally it was obtained from an oil-lamp, the flame from which was acted on by a current of oxygen gas; subsequently oil gas was substituted for the liquid oil; but now the gas which is made for lighting the streets of towns is employed to produce the flame, and the brilliancy is increased by a current of air ingeniously introduced. The mode of admitting fresh air, and carrying off the products of combustion, constitute the difference between this and the common gas-light. It is found to be a cheap mode of producing a bright light; but as a similar effect may be produced by other means, the distinctive name of bude-light is not now much employed.

BUENOS AYRES, the capital of the republic of La Plata, carries on a large trade with France, importing from thence linen, wearing apparel, toilet articles, shoes, dressed leather, woollen and silk goods, &c. The imports from England and Germany are smaller in amount. The imports from France in 1844 amounted to 769,280*l.*; the exports to France to 411,168*l.* The total exports from Buenos Ayres in 1843 were valued at 1,659,206*l.* Buenos Ayres is the outlet for the produce of the vast herds of cattle which roam over the Pampas of La Plata; from this source we imported in 1848 about 115,000 hides, 13,000 lamb skins, and 80,000 cwts. of tallow.

BUILDING. In the practice of civil architecture, the builder is the individual who comes between the architect who designs and the artisans who execute the work; and building is essentially a manufacture. Referring to such articles as BRICKWORK, CARPENTRY, FLOOR, FOUNDATION, HOUSE, JOINERY, PLASTERING, ROOF, &c., for a few details relating to the art of building, a few words of a general nature may be here introduced.

The article BRICKWORK relates simply to the modes of arranging the separate bricks or component parts into a solid and adhesive wall. The builder must further combine the several portions of a wall broken or separated by openings for doorways and windows, and the several walls of a house, into a self-sustaining structure, every part of which should, as far as possible, lend support to every other part. The effect of openings, for example, must be counteracted by *inverts* or *inverted arches* beneath them, and *discharging arches* over them; these being either left visible or concealed by a facing of other brickwork, according to circumstances. *Wood bricks*, or blocks of seasoned wood, must be inserted in the walls to facilitate the fixing of door and window frames, or other woodwork. *Lintels*, or bars of wood surmounting square-headed apertures, are sometimes used in lieu of arches, but should always be surmounted by discharging arches. *Templates* are pieces of wood larger than wood bricks, inserted to support and distribute the pressure of the ends of beams, &c., and *wall-plates* are still longer pieces let into the brickwork to support the floor-timbers. *Bond-timbers* are sometimes inserted to distribute and equalise strain; but the liability of timber to shrink and swell, to rot and to be destroyed by fire, render it desirable to insert it in brickwork as little as possible, and that under such circumstances that its total destruction may not affect the stability of the walls. The plans recently introduced for preserving timber [TIMBER, PRESERVATION OF] somewhat lessen the objections to its use.

In the erection of any building it is desirable to carry up all the walls as equally as possible, to avoid the risk of unequal settlement. Interior partition walls are often formed of lath and plaster, on a timber framing; but, where weight is not an objection, of *brick-nogging*, or brickwork 4½ or 3 inches thick, strengthened by timber framing. Some use half-brick walls, built in cement, and strengthened with iron hooping laid in a few of the joints. The tops of brick walls are protected by COPING, which should be so formed as to throw off water.

Other modes of building than with brick are noticed elsewhere. [MASONRY.] *Flints* and *earth* are also advantageously employed in certain districts. Buildings of flint depend much for their strength upon the quality of the mortar or cement employed, and upon the judicious introduction of bonding-courses and quoins or angles of brick or of larger stone. Building with compressed earth, or building *en pisé*, is a very cheap mode, long used in some parts of France, but less known in this country than it deserves to be. Another mode of building well adapted for cottages in which no great strength is required in the walls, is with *hollow walls* of brick laid on edge, but otherwise arranged like ordinary Flemish bond. In this plan a space of 3 inches is left in the middle of the wall between each pair of stretchers. Walls thus constructed exclude damp and cold far better than solid walls. For modes of constructing FIRE-PROOF BUILDINGS, see that article.

BULKHEADS, which divide the hull of a ship into several water-tight compartments, are formed with the view of preventing the whole hull from being filled with water in case of a fracture or leak. Mr. C. W. Williams, in a paper communicated to a parliamentary committee on steam vessels, states that it has been found impracticable to make bulkheads of timber, on account of the liability of timber to shrinkage and leakage. Bulkheads of iron plates obviate this objection. Vessels are divided into two, three, four, or five water-tight compartments, by one, two, three, or four bulkheads; the more there are the greater the safety; but as they interfere with free passage from one end to another of the vessel, and as they entail greater expense and consumption of material, there soon arises a practical limit to the number. Mr. Williams recommends four bulkheads and five compartments for a steam-boat. The central compartment would hold the engine, boiler, and other machinery; the two compartments next to the centre would form the fore and after cabins or the fore and after holds, according as the steamer is a passenger or a trading vessel; while the two end compartments need not come up so high as the main-deck, on account of the deck at these parts being lifted higher up above the water than near the waist or middle of the ship.

BULLETS. The general mode of making bullets is noticed under SHOT-MANUFACTURE. We may, however, here state that a patent for making bullets was taken out in America in 1849, in which the bullet is formed by punching. The end of the punch has a hemispherical cavity, and a die is used which has a similar cavity. A strip of sheet lead is laid on the die, and the punch is brought down upon it with a force sufficient to sever a small piece of lead, and to form it into a globular shape by means of the two hemi-spherical cavities.

Several years before, however, in 1840, Mr. David Napier had patented a method, somewhat similar in principle, but more comprehensive, for making bullets in which great accuracy of form may be required. The machinery consists of two sliding plungers, placed horizontally and opposite to each other; each carrying a hemispherical die. The meeting and closing of the two dies give a perfectly spherical form to any substance compressed between them. In the centres of these plungers are two sliding plugs, which, in the retrocession of the plungers, are urged forward by a spring placed behind them, and drive out the compressed ball. An alternating motion backwards and forwards is given to the plungers. Strips of lead having projections, prepared either by rolling or casting, are supplied to the machine, the continuous pressing of which converts the projecting pieces of lead into perfect spheres, held together by a thin film of lead. The strips are then taken to a small hemispherical punch, working vertically into a circular bed the same size as the balls; and on bringing down this punch by means of a foot treadle, the balls are cut out, fall through the bed, and roll down a trough into a proper receptacle. This method of making bullets by compression was, we believe, at one time adopted by the government at Woolwich, the apparatus being worked by steam.

BULLION. This term is strictly applicable only to uncoined gold and silver, but it is frequently used in discussions relating to subjects of public economy to denote those metals both in a coined and in an uncoined state. At the Bank of England, all persons may demand of the issue department notes in exchange for gold bullion at the rate of *3l. 17s. 9d.* per ounce of standard gold, to be melted and assayed by persons appointed by the Bank, at the expense of the persons who tender the bullion.

Bullion is also applied as a distinctive name of particular kinds of fringe.

BU'NIUM. The *pig-nut* of the rural districts is the nearly globular root of the bunium plant, of a black or chesnut colour on the outside, and white inside. It has an aromatic sweet taste, and is frequently dug up and eaten by children. Pigs are very fond of these nuts, and get fat when allowed to feed on them. When boiled, they are a pleasant and nutritious food. Roasted, they are preferred by some people to chesnuts, and are often in this country and on the continent added to soup or broth.

BUOYANCY is the power which certain materials have of being supported at the surface of a fluid, so as to sink in it as much only as a part of their depth or thickness. Thus ice, some woods, &c., are said to have buoyancy in water, and almost all solid bodies have the power of floating on mercury. The term is frequently used to designate the weight which a solid mass of wood, or a vessel of wood or metal, will support in water. A brief explanation of the principle of buoyancy is given under HYDRAULICS. The propositions relating to it are useful in determining the amount of volume which would have buoyancy sufficient to raise a sunken ship; or in determining the dimensions of a floating bridge which may support a given weight of troops or artillery.

BUOYS are vessels formed of wood, cork, or some other substance which is specifically lighter than water. They are moored so as to float on the water at some certain spot, in order to point out the course or channel that a vessel should follow. Buoys are also used for the purpose of marking the situation of ships' anchors to which they are attached, and thus facilitating the future recovery of the anchor and cable in cases where the latter has been broken, or where it has been cut, in order to provide on emergencies for the safety of the ship, when circumstances do not admit of the anchor being weighed into the vessel. The first description of buoys are denominated public buoys, and the last private buoys. Another kind of buoys are those placed in harbours to mark the situation of mooring-chains to which ships frequenting the port are made fast.

Until the reign of Queen Elizabeth all public buoys in this kingdom were under the management of the Lord High Admiral; but since 1594 they have been under the control of the Trinity House. The amount of revenue annually collected for the use of buoys by the Trinity House corporation is between 11,000*l.* and 12,000*l.* The charge made is according to the tonnage of the vessels frequenting the ports in or leading to which buoys are placed: the rates vary according to circumstances, and are highest in the port of London, where British and foreign *privileged* vessels (those belonging to countries with which we have 'reciprocity treaties') pay one penny per ton; and foreign vessels not privileged pay two pence per ton.

The buoys which are sometimes used as life-preservers are noticed elsewhere [LIFE-BUOYS.]

BURETTE, is an instrument invented by M. Gay-Lussac, for the purpose of dividing a given portion of any liquid into 100 or 1,000 equal parts. It consists of a measure of definite capacity, a graduated tube, and another tube of smaller bore attached to the former. It is much used in French chemical factories, but is scarcely known in England.

BURNING GLASSES AND MIRRORS. A convex lens or a concave mirror, by collecting a quantity of light within a small space at the focus, will also, if the lens or mirror be of considerable size and the light very strong, as that of the sun, collect a quantity of heat sufficient to destroy almost any substance. This property has been long known. Among the earliest attempts to produce considerable effects by burning instruments is that of Tschirnhausen, who, about the year 1700, made a glass lens 33 inches diameter and 7 feet focal length, by which the concentrated light of the sun, in a short time, burnt wood, melted small pieces of metal, vitrified slate, &c. In the year 1747 M. Buffon constructed an apparatus which, on a concave surface, carried 220 plane mirrors; with this the sun's light burnt wood at the distance of 200 feet, and melted metals at 50 feet. About the year 1800 Mr. Parker, in London, executed a burning lens of flint glass 3 feet diameter and 6 feet 8 inches focal length, with which, by concentrating the sun's light, he fused gold in three seconds, steel in 12 seconds, and limestone in 55 seconds; and, by the heat thus produced, a diamond weighing 10 grains was reduced to six grains.

As a source of heat, the burning glass has not yet been made available in manufactures, except in a few trifling instances: but there is nothing irrational in supposing that it may one day subserve useful purposes.

BURNLEY is one of the busy cotton-spinning towns of Lancashire. The trade of the town was formerly confined to woollens: but the cotton manufacture is now the staple. At the present time (1850) there are about 30 cotton spinning and weaving mills; there are no cotton bleaching or dye works; but there are two calico printing establishments. There are also three worsted mills. Besides the above, Burnley contains four corn mills (one of them very large), iron foundries, machine-making works, brass foundries, roperies, tanneries, breweries, and collieries.

The Leeds and Liverpool canal, and the East Lancashire and other railways, afford media for the conveyance of goods through the whole line of country, from the German Ocean to the Irish Sea. Besides its manufactures Burnley sends coal, freestone, and slate from the vicinity.

BURNT-EAR, in corn, is a disease in which the fructification of the plant is destroyed and as it were *burnt* up: hence its English name and the corresponding names of *charbon* in French and *brand* in German. In *burnt-ear* the black powder which appears in the ear is external, and the grain has either never been formed, or its coat has been destroyed, so that the whole ear appears black or burnt. The powder also has no smell, and, being easily blown away by the wind, or shaken off in the reaping, little of it adheres to the corn or is mixed with it when ground; and, except the loss of so much grain as would have been contained in the sound ears, no great detriment arises to the quality of the corn. Microscopic observations show that the black powder consists of the minute germs or sporules of a parasitical fungus, which are developed in the growing ears and live on its substance. The best preservative against this disease is to drain the land well and keep it in good heart.

BURSLEM, in Staffordshire, often receives the name of the 'Mother of Potteries,' having been the first, and for a long period the chief of the pottery towns. From an early period it has been distinguished for the variety and excellence of the clays in its vicinity. All the subsoil of the town is clay, varying from two to ten feet in thickness; it is called in the neighbourhood *tough Tom*, and is employed in the manufacture of red, brown, and yellow wares. Below the subsoil is a very thick stratum of fire-clay, of which the saggers or baking vessels for the pottery kilns are made. Below the fire-clay is coal. Most of the early improvements in the pottery manufacture were made at Burslem; and the town took the lead in this art, until Wedgwood removed thence to Etruria. Longport is now so closely united to Burslem, that the two form in effect one large town, every part of which is occupied by the pottery works, the houses of the workpeople and employers, or the shopkeepers. No town in England, perhaps, is more dependent on one particular branch of manufacture than Burslem is on that of porcelain and earthenware. There are at the present time in the whole parish nearly forty pottery establishments; besides glass-works at Longport.

BURY is one of the active manufacturing towns of Lancashire. The manufacture of woollen cloth became a staple article of trade in this place so far back as the fourteenth century, and flourished to such an extent that in the reign of Elizabeth one of her aulnagers was stationed in the town to stamp the cloth. Up to a much later date woollens were almost the sole manufacture of the place; but upon the introduction of the cotton trade into the county many of the inhabitants became weavers of cotton fabrics, and the woollen trade has been gradually retiring into Yorkshire and other parts of the country where the cotton manufacture is less paramount. The different branches of the cotton manufacture, owing to the vicinity of Bury to the Manchester market, and the abundant supply of coal and water, are carried on to a considerable and increasing extent in this and the adjoining township.

Several important improvements in the cotton manufacture took their rise in this place. A new method of throwing the shuttle by means of the picking-peg instead of the hand, and thence called the fly-shuttle, was invented by John Kay, a native of the town: and in 1760 his son, Robert Kay, invented the drop-box, by means of which the weaver can at will use any one of three shuttles—an invention which led to the introduction of various colours into the same fabric, and made it almost as easy to produce a fabric consisting of different colours as a common cloth of only one. Bury is indebted for one branch of its present trade to the father of the late Sir Robert Peel, who established his extensive print-works on the banks of the Irwell, near this town; he resided at Chamber Hall, in the immediate vicinity, where, or at a smaller house close by it, the late Sir Robert Peel was born.

There are at the present time in Bury more than a dozen large factories for spinning and manufacturing cotton, several large woollen manufactories, two calico-printing and bleaching establishments, and two dye-works. Besides the different branches of cotton and woollen manufactures, there are three large foundries, several smaller ones, and manufactories of hats and other articles.

BUSHEL. By the act of 1824 the standard gallon contains 10 pounds avoirdupois of pure water. Eight such gallons make a bushel, and eight bushels a quarter. This, by the other provisions of the act, made it contain 2218.2 cubic inches very nearly.

BUST, in sculpture, means a statue truncated below the breast. As a question of fine art, the production of a bust depends on the same exercise of taste and refined judgment as that of a statue. As a question of mechanical execution, we shall have occasion in a later article to describe Mr. Cheverton's remarkable mode of carving busts by machinery. Busts in bronze or other metal, in biscuit or other kinds of porcelain, and in plaster, are produced by casting.

BUTTER is the fat or oleaginous parts of the milk of various animals, principally of the domestic cow. The milk of the cow consists of curd, whey, and butter, and is esteemed chiefly in proportion to the amount of butter, which differs much in that of different breeds.

For the making of butter, the milk, brought into the dairy from the milking-shed, is strained through a fine sieve or cloth into shallow pans, or troughs lined with lead, which are filled to the depth of four or five inches. These should be in a place sheltered from the sun, but having a thorough draught of air by means of opposite wire windows. The floor should be kept moist in summer, to produce coolness by evaporation; but in winter a small stove is an advantage, provided smoke and smell be avoided. After standing twelve hours the finest parts of the cream will be found to have risen to the surface; and this, if skimmed off, will furnish a very delicate butter. More generally however the milk is allowed to stand twenty-four hours, and then the cream is collected, either by skimming or by letting off the thin milk from beneath it by opening plugs in the troughs. The cream is put in a deep earthen or stone-ware jar, which should be glazed, but not with lead; and more is added every day until there is sufficient to churn. The cream is usually stirred from time to time, to promote a slight acidity, which facilitates the process of churning.

There are many varieties of churn [CHURN]; but most of them have a beater or fan which agitates the cream. The barrel of the churn should not be more than two-thirds full of cream. In the course of an hour's agitation or churning, small kernels of butter are found among the cream, and these become gradually united into a solid mass, leaving a fluid residue called *butter-milk*, which is set aside for domestic use, or for feeding pigs. The butter is then removed to a shallow tub, well beaten with the hand or a flat wooden spoon, and repeatedly washed with clear spring water, until all the remaining butter-milk is removed from it; after which, if intended to be sold fresh, it is made up in rolls or cakes for the market, or salted and put into casks if intended for keeping. Cakes or pats of fresh butter are often impressed with some device from a carved wooden print, resembling a large seal. In Cambridgeshire butter is made up into rolls a yard long, and passed through a ring of a certain diameter, for the convenience of dividing it into small portions without weighing. In salting butter the quality of the salt is of great importance; and some, instead of simple salt, use half an ounce of dry salt, pounded fine, two drams of sugar, and two drams of saltpetre, to every pound of butter. As a cask is gradually filled up, every addition is carefully incorporated with the preceding portion. Should it shrink in the cask, melted butter may be poured round it to fill up the interstices.

Butter may be preserved for domestic use, without salt, by melting it very gently, without boiling; which causes the watery particles to evaporate, and the curd, which is always present in small quantity and is a principal cause of rancidity, to fall to the bottom. The clear butter is then poured into an earthen vessel, and covered with paper; and a piece of bladder or leather is tied over it to exclude the air. Butter thus prepared resembles lard in appearance, loses some of its flavour, but is much superior to salt butter for ordinary purposes.

In Devonshire, instead of the ordinary mode of raising cream in shallow pans, the milk is, after standing twelve hours, exposed to heat, without boiling, by which a thick scum called *clotted cream*, more solid than cream, but not so solid as butter, is thrown up. A very slight agitation converts it into butter, another mode, which is followed in parts of Holland, Scotland, and Ireland, is to churn the milk and cream together, by which, it is said, more butter is produced.

Much attention is paid to the most minute circumstances in the manufacture of butter, especially in all that relates to cleanliness. In Switzerland men are chiefly employed in milking and in making butter and cheese; the women only cleaning the utensils and carrying green food to the cows when kept in the stable. The gradually extending use of the thermometer is an important improvement in dairy practice; and probably the electrometer may be found similarly useful, as the state of the atmosphere in reference to electricity evidently has a powerful influence on the making of butter. The nature of the pasture is also important. The best butter is produced from cows fed in rich natural meadows; and some plants which grow in poor and marshy soils impart a disagreeable flavour to the butter, as also do turnips and other roots, and most cut grasses. This may be in some measure obviated by adding a little water and saltpetre to the milk, or, it is said, by giving salt to the cows with their food. The best winter butter is made where the cows are fed with good meadow hay, or aftermath hay, which contains few seedstalks. The colour varies much from different cows, and from the same at different times. Arnotto or the juice of carrots is sometimes mixed with the cream to impart a deeper yellow.

Upon an average, four gallons of milk produce sixteen ounces of butter; and, to be profitable, a good dairy cow in England should produce six pounds of butter per week in summer, and three pounds in winter, allowing from six weeks to two months for her being dry before calving. This makes 120 lbs. in twenty weeks after calving, and 80 lbs. in the remaining time, or 200 lbs. in the year.

Whey Butter is an inferior kind made in some cheese dairies from the oily portion of the milk skimmed from the whey; it is sold chiefly to labourers, seldom comes to market, and is totally unfit for salting and keeping. *Ghee*, or fluid butter, forms one of the staple productions of many districts in India.

All the butter that is produced in England is consumed at home, and a large quantity is imported from Ireland, Holland, and other countries. The consumption of butter in London is estimated by M'Culloch at 15,000 to 16,000 tons annually, of which 2000 tons are supplied to shipping. At 10*d.* per lb. for 34,400,000 lbs., the value consumed of this article amounts to 1,433,333*l.* The consumption per head in this estimate is assumed to be 5 oz. weekly, or 16 lbs. per annum. In 1835 the imports from Ireland were 827,009 cwts., valued at 3,316,306*l.*; but since that date the imports of Irish butter do not appear in the Government tables.

Almost all the butter exported is derived from Ireland. In 1849 the exports of this commodity amounted in value to 210,604*l.*, of which the largest quantities were sent to Brazil, West Indies, and Portugal. The importations of foreign butter, in 1849, amounted to 282,501 cwts., of which two-thirds came from Holland.

A few interesting details concerning the Irish butter-trade will be found under CORK.

BUTTERS, VEGETABLE, the name given to the concrete oil of certain vegetables, from its resemblance to the butter obtained from the milk of animals, and from being employed for similar purposes. The chief vegetable butters are produced by the *Bassia butyracea* and other species of the genus Bassia. [BASSIA.]

BUTTERS, (in pharmacy), is an obsolete name for the hydrochlorates of the metals, such as antimony, arsenic, bismuth, tin, and zinc.

BUTTON MANUFACTURE. Gold, silver, brass, copper, pewter, mother-of-pearl, hard wood, bone, ivory, horn, leather, paper, glass, silk, wool, cotton, linen, thread, are all formed into buttons, and the manufacture is carried on to a very great extent. Metal buttons with shanks are stamped out of a plate of the material; and each circular piece or 'blank' is trimmed and smoothed. The shanks are made of wire by an ingenious machine and are soldered on to the blanks. After a little further preparation, the buttons (if of the common gilt kind) receive a coating of gold [GILDING], which is now often effected by the electro process. White metal buttons, such as those on soldiers' dresses, are cast in moulds containing ten or twelve dozen, and the shanks are placed in the moulds previously to casting, so that when the buttons are cast the shanks are fixed at the same time. Mother-of-pearl buttons are cut out of the pearl shell by a cylindrical saw; and the shanks are fixed by a kind of dove-tailed projection of the wire in a hole drilled in the shell through one-half its thickness.

Buttons without shanks are made of mother-of-pearl, wood, bone, metal, &c., the metal ones being stamped, and the rest turned. They have four holes through which the thread is passed to fix them on the garment. These holes are stamped in metal buttons, but they are drilled in those which are made of other materials. The holes are drilled while the buttons are in the lathe: four long drills are made to converge towards the button, and thus the four holes are all drilled at once. The buttons most extensively used at present are those covered with cloth or silk, the manufacture of which has arrived at great perfection. Most varieties of coat-button now consist of two circular blanks of iron, one of thick pasteboard, one of thick canvas, and one of silk or florentine. All these are cut out separately with great rapidity, by a stamping press from sheets of the respective materials. Into a kind of die or cell is placed, first, the silk or florentine, then a disc or 'blank' of iron, then the pasteboard, then the canvas, then the other piece of iron—all superposed. A stamping-press, of beautiful construction, fixes all these together, without the aid of any other mode of fastening.

Buttons made of wire rings covered with thread or with linen, and metal buttons made iridescent of minute grooves, are among the varieties of the manufacture.

A singular method was introduced a few years ago, of imitating covered cloth buttons by a layer of flock, such as is used in paper hangings. In the first place, thin sheets of metal are coated on one side with copal varnish thinned with turpentine, and coloured according to the colour of the flock to be employed. After being heated in an oven to 150° Fahr., and then allowed to cool, the surface is coated with a kind of paint formed of white-lead, linseed oil, gold size, and colouring matter. While in this wet state, a quantity of flock is sifted over the surface, and allowed to remain on it twelve hours, by which time a film of flock will have adhered firmly to the metal. The loose flock being shaken off, the sheet is fitted to be cut up into collets or discs for the backs of buttons, to be made in the usual way.

Mr. Prosser's method of making buttons and other small articles of compressed clay was patented in 1840. Clay, clayey earth, or clay combined with a small portion of flint or felspar to give it hardness, is thoroughly dried and ground to a fine powder. The powder is passed through a sieve having about two thousand perforations in a square inch: all particles too large to pass through the perforations being rejected. For some coarser purposes a coarser sieve may be used. Buttons and other small articles are made of this powder by dies, or moulds and a fly-press. The fly-press is firmly secured to a strong bed or frame; and a die, carrying on its under face the form in reverse (i. e. hollow instead of relief,) proposed to be given to the top of the button, is screwed to the follower of the press. A second tool or die of a kind of T shape, with an impress of the back of the button, fits loosely into a corresponding recess in the bolster. Below the press there is a treadle supported on a fulcrum near its centre, from one end of which a rod passes up through a small hole in the bolster to the lower die or tool. The hollow or recess in the bolster in which this tool rises and falls is of such a depth as to be an exact measure of the quantity of powder necessary for the formation of a button. The hollow in the mould being filled with powder, and the powder squared off to an exact level with the top of the mould, such power is applied to the press as will bring down the tool with a force of about 200 lbs. on the square inch, upon the powder lying in the mould. The powder is by this means compressed into a very dense, hard, and durable substance, having on its surface the device imparted to it by the die. If the button is to have a metallic shank attached to it, a recess is formed at the back of the button for its reception, by a corresponding projection on the face of the lower die. If the button is to have holes similar to a brace-button, the dies must have such projections as will form these holes while the powder is being pressed into the mould.

In the course of a year or two after this patent was obtained, no less than 5000 gross of these buttons were made weekly, at Minton's porcelain works in Staffordshire.

The Vicomte de Serionne took out a patent in 1850, for a somewhat complicated mode of making buttons, which should have a sort of crystalline appearance. They are made of felspar, basalt, lava pumice, granite, or flint. These minerals, or the one to be adopted, is reduced to powder, and made into a paste with salt and flour; the paste is pressed into a mould, of which the upper and under parts give the device to the button; and by subsequent modes of treating the surface, the button assumes either a transparency, or an agate-like opacity.

Birmingham is the great seat of the Button manufacture in this country. [BIRMINGHAM.] It is supposed that at the present time (1851) there are upwards of 5000 persons employed at Birmingham in making buttons, of whom rather more than half are women and children.

BUTTRESS, a projecting support to a wall, most commonly applied to churches in the Gothic style. Buttresses are usually finished with a sloping top, and divided into several heights, each of which projects less from the wall as they ascend. The buttresses of Gothic buildings are variously decorated. The most superb buttresses ever executed in this country belong to Henry VII's chapel at Westminster Abbey.

BUTY'RIC ACID, a colourless acid liquid, which exists in butter. It combines with water, and evaporates readily in the open air. It consists of carbon 8, oxygen 3, hydrogen 6. It combines with different bases to form salts, called *butyrates*, few of which are of importance. In intimate relation with this substance is *butyrine*, a yellow liquid procurable from butter.

BYSSUS. Recent investigations have determined that byssus is linen: at least so far as the term has been applied by Greek and Roman writers to mummy-cloth. Herodotus states, that the Egyptians wrapped their dead in the cloth of the byssus; and it has been shown, by microscopic observations, that every specimen of mummy-cloth yet examined is made of linen fibre.

Byssus is also a name given to the long silky fasciculus of filaments by which some of the bivalve shell-fish (such as mussels, hammer oysters, &c.), are moored to submarine rocks. Some authors have regarded these threads as a peculiar secretion spun as it were by the animal. De Blainville, however, asserts them to be an assemblage of muscular fibres, dried up in one part of their extent, but contractile and living at their origin, as they were throughout at the period of their first attachment. The Byssus in the great *Pinna* of the Mediterranean is largely developed. It is manufactured in Italy into various articles, as gloves, &c., of which specimens are preserved in many museums. The *byssus* or *beard* of the mussel is familiar to all.

C

CABBAGE. The cabbage is not only valuable as a food for man, but it is an important aid to the operations of the grazier. When given to cattle or sheep, cabbages should be sliced in the same manner as turnips or beet-root. When milch cows are fed with them, all the decayed leaves should be carefully taken off and given to store cattle or pigs; for these are the chief cause of the bad taste which the milk and butter acquire from this food. For bullocks, cabbages and oil-cakes are excellent food, and increase their flesh rapidly. For sheep, cabbages should be sliced, and given to them in troughs in the field where the cabbages grow, or on grass land which requires to be manured.

In Germany there is an immense consumption of the large white cabbage in the form of the national mess, called *sauer kraut*. This is prepared by slicing the cabbage, and placing them in a tub with alternate layers of salt and allowing them to ferment. This preparation, when washed with soft water and stewed with bacon or salted meat, is a very wholesome dish, and much relished by those who have been early accustomed to it. In long voyages it has been found to be an admirable preservative from the sea-scurvy.

CABIN, is an apartment or room in a ship. In large vessels, the admiral's and captain's cabins extend across the ship near her stern, and are usually divided into two, termed the fore-cabin and after-cabin. Those belonging to the junior commissioned and warrant officers are ranged along the side of the ship, having an area of from 5 to 6 feet in width, and from 6 to 7 feet in length.

In frigates the captain's cabin is on the main-deck; and the gun-room, or after part of the lower deck, is given to the officers; but in two-decked line-of-battle ships the captain takes the cabin under the poop, and the officers the great cabin on the upper gun-deck, which is called the ward-room. In three-deckers this large apartment is appropriated to the admiral, and the officers take the corresponding one on the middle gun-deck. The partitions by which all these cabins are inclosed are called *bulk-heads*, which are instantly removeable when the decks are ordered to be cleared for action.

CABINET MAKING. [FURNITURE MANUFACTURE.]

CABLE. [CHAIN-CABLE; ROPE.]

CABUL, or CAUBUL. The industry and commerce of this country have been already briefly described. [AFGHANISTAN.]

CACAO, the bruised seed of the *Theobroma*, is more familiarly known as COCOA, under which name we shall describe it.

CACTUS. Some kinds of cactus render useful services to man. In most of those found in tropical America, the stems are filled with an abundant insipid wholesome fluid, and their fruit is succulent, and in many cases superior to that of European gooseberries. In cases of fever in their native countries they are freely administered as a cooling drink; and being bruised they are esteemed a valuable means of curing ulcers.

Opuntia Tuna is the species of cactus which nourishes the cochineal insect. According to Humboldt it is in much esteem in Peru as the food of that valuable insect.

CADIZ, a large commercial town on the S. W. coast of Spain, enjoyed for a long time a high degree of prosperity, arising from its trade with the Spanish American colonies. In 1792 the imports from Spanish America were to the amount of 7,295,833*l.*; in 1791, the amount of gold and silver, coined and uncoined, received from the same quarter exceeded 5,300,000*l.* This commercial activity was wholly destroyed by the defection of the Spanish possessions in America. The foreign trade of Cadiz, which is now in a state of great depression, consists of the importation, in Spanish bottoms, of colonial produce from Cuba, Puerto-Rico, and the Philippine Islands; cocoa, hides, cochineal, indigo, and other produce from South America. Salt-fish is imported from Newfoundland in English vessels. Linens, silks, and woollen cloths, iron hoops, tin, glass, hardware, and earthenware, butter and cheese, are imported from England, Germany, and France, mostly in Spanish ships; staves are supplied by the United States in vessels belonging to those states; and timber is imported from Russia and Sweden, in foreign bottoms. The chief articles of export are wine, salt, fruit, oil, wood, cork, and quicksilver, which are usually shipped in vessels bearing the flag of the country to which the shipments are made. The manufactures carried on in the city consist of soap, glass-ware, coarse woollens and linens, cotton and silk fabrics, and hats; there are likewise some sugar refineries and tanneries.

CA'DMIUM, is one of the recently discovered metals. It occurs in ores of zinc, from which it is usually obtained. It has the colour of tin, is brilliant, and susceptible of a fine polish. Its fracture is fibrous, and it crystallizes readily in regular octahedrons; while solidifying its surface is covered with arborations like fern leaves. It is soft, easily bent, filed, and cut; it stains substances upon which it is rubbed, like lead. When bent, it gives a peculiar crackling noise, like tin. It is very ductile, easily drawn into wire and beaten into thin leaves. Its specific gravity after fusion is 8·604, but when beaten 8·694. Cadmium melts below a red heat; and, at a temperature a little above that of boiling mercury, it boils and distils in drops. The vapour of cadmium has no particular odour. Like tin, it is slowly acted upon by the air, but is eventually tarnished by it.

Cadmium combines with several other elements; but these compounds have not yet become extensively valuable in the arts.

CAEN, in Normandy, is famous for the manufacture of lace, angola gloves, and cutlery; linen, woollen and cotton stuffs, hosiery, porcelain, oil, paper, and leather, are also made. The town is a depôt for salt, and has large timber and ship-building yards. About 800 vessels arrive annually, of which 160 are freighted with salt. The other articles of commerce are corn, wine, brandy, cider, clover-seed, hemp, horses, fat cattle, butter, iron, hardware, mill-stones, building stone, and granite for paving.

CAERMARTHENSHIRE. The southern part of this county, bordering upon Glamorganshire and the sea, forms part of the great coal-field of South Wales. The coal is chiefly what is called stone coal; the large coal of this quality is used for drying hops and malt; the small coal, called culm, for burning limestone. Towards the coast the coal is more bituminous. The coal-field of South Wales lies in a basin of mountain or carboniferous limestone, and the northern outcrop of this limestone crosses Caermarthenshire in a waving line E. and W. From this limestone is obtained marble for chimney-pieces, stone for tomb-stones, and lime for manure.

CAERNARVONSHIRE, in North Wales, is rich in minerals. There are copper-mines at Great Orme's Head, in the vale of Conwy a little west of Llanrwst, in the vale of Llanberis, and near Pont Aberglasllyn. Lead and calamine are obtained in the vale of Conwy near the junction of the Llugwy with the Conwy, aud in that part of the county which lies east of the Conwy. Mill-stones are dug in the vale of Conwy. Slates are found in various parts of the county, and form one of the chief articles of export. The finest are those on the west side of the ridge of the Snowdonian mountains, and they become finer as they descend towards the sea. Not only roofing-slates and writing-slates are procured from these mines, but inkstands and other fancy articles are made. Slabs are procured large enough for tomb-stones and paving-slabs.

CAFEIC ACID exists in coffee, which owes to it a part of its odour. It is combined with lime, magnesia, alumina, and iron, forming salts or *cafeates* of those bases. The alkaline cafeates are of a pure brown colour without any admixture of green, and by evaporating the solutions they are obtained in the state of brown horny masses. *Cafeine* is another peculiar substance obtained from coffee, in soft, silky fibres, which have a very bitter taste.

CAIRN, or CARN, a heap of stones thrown together in a conical form. Lhuyd, in his 'Additions to Camden's Britannia, in Radnorshire,' asserts that in the Cambro-Britannic *Kaern* is a primitive word appropriated to signify such heaps of stones. Cairns and tumuli of earth were the common monuments which the ancient Britons erected in honour of their great men. Pausinius mentions monuments of collected stones, especially near Orchomenus, in Arcadia, for persons who had fallen in battle.

CAIRO. The industry and commerce of this important city are noticed under EGYPT.

CAJEPUT OIL, is produced chiefly from the *Melaleuca Cajuputi*, a native of Amboyna, and other East India islands. The oil is obtained by distillation of the leaves and branches, which are collected the night before they are subjected to this process. It is very limpid, pellucid, and of a light or yellowish green colour. In its action on the human frame Cajeput Oil participates in the properties of other volatile oils, and is rubefacient externally; stimulant, and anti-spasmodic, when taken internally.

The Cajeput Tree, a native of the East India Islands, was at one time supposed to yield the oil of commerce. Roxburgh asserts that it possesses little or no fragrance in its leaves, and that it is seldom or never used for the distillation of the oil which is used in the European markets.

CALIMINE. [ZINC.]

CA'LAMUS is the genus of palms whose different species constitute the *rattan canes* of commerce.

The species are principally found in the hotter parts of the East Indies, where they grow in the forests, climbing over trees and

KNIGHTS CYCLOPÆDIA OF THE Industry of all Nations.

bushes to a greater extent than any other known plants. The stem of *Calamus verus* is described as being 100 feet long; that of *C. oblongus* 300 to 400, of *C. rudentum* upwards of 500; and of *C. extensus* as much as 600 feet; Rumphius even states that one kind of Calamus attains the extraordinary length of 1,200 feet. It is closely covered over by the tubular bases of the leaves, through which it is drawn by the cane-gatherers when green; afterwards it is dried in the sun, and then is ready for market. From three to four millions of these canes are imported into this country annually. They are extensively used for the sake of the hard flinty coating of their stems, which are readily split into strips, from which the bottoms of chairs and similar articles are manufactured. It is not possible to say from what particular species the canes of the shops are obtained, it being probable that many are gathered indiscriminately. The flesh that surrounds the seeds is a delicate article of food; and the young shoots of some of the species while still tender, are roasted or boiled, chopped small, and, being fried with pepper and gravy, are said to furnish a very delicate dish.

The greater part of the *Dragon's Blood* now met with in commerce is obtained from several species of this genus. They are natives only of Hindustan, Cochin China, and the Moluccas. The ripe fruits are covered with a reddish-brown, dry, resinous substance. In this state they are collected, and allowed to remain till the resin drops off. The resin is afterwards melted, either by the natural warmth of the air or by artificial heat, and then moulded into the different forms in which it occurs in commerce. Dragon's Blood possesses no astringent properties, as was once supposed to be the case, owing to *kino* being confounded with it. It is now seldom used internally, but it is added to tooth-powders. It is however employed as a colouring matter and an ingredient in varnishes.

CALCAREOUS SPAR is one of the names given to the rhombohedral crystals of carbonate of lime. The specific gravity of the purest crystals of this mineral is 2·721; and the hardness is between gyps and fluor spar. It is of itself colourless, but frequently occurs of various tints of yellow, green, red, brown, and even black, from the admixture of impurities. Its glance is mostly vitreous. The lead mines of Derbyshire and Cumberland, and of Andreasberg in the Harz, are noted as affording the most beautiful crystals, and the greatest diversity of forms.

Every visitor to the British Museum has opportunities of inspecting exquisite specimens of calcareous spar.

CALCEDONY. [AGATE.]

CALCINATION, is the separation of the volatile from the more fixed parts of a body: thus bones which are heated till they become black are termed *burnt bones;* but when, by the further operation of heat, they become white, they are called *calcined bones.* But what were formerly termed metallic calces or calcined metals are now described as metallic oxides.

CAL'CIUM, a peculiar metal, of which *lime* is the well-known oxide. It was first obtained by Davy, in 1808, by the action of voltaic electricity on a small mass of chalk. That calcium is a white combustible metal is nearly all that is known respecting it; but many of its compounds with other elements have been long known and extensively employed. [LIME.]

CALCULATING MACHINES. Before computers had attained great proficiency in performing arithmetical operations by the pen, machines by which the results of such operations could be obtained by inspection were in almost constant use. The principal of these were the Roman *abacus*, which continued to be employed in the south of Europe till the end of the 15th century, and in England to a later period; and the *Schwan-pan*, which in China has long been the principal means of making computations. [ABACUS.] For the operations of multiplication and division the ivory rods of Napier, commonly called *Napier's Bones*, were for a time used; and, for solving trigonometrical problems, *Gunter's Scale* or the *Logarithmic Scales* were once very generally employed by navigators.

The celebrated Pascal constructed, it is said, when only 19 years of age a machine for executing the ordinary operations of arithmetic. Subsequently to the time of Pascal, Leibnitz invented a machine by which arithmetical computations could be made; but no account of it appears to have been published.

All former contrivances for performing such operations may be said to have been cast in the shade by the machine invented by Mr. Babbage, which, should it be completed, will constitute one of the most superb monuments of human ingenuity. Not only are its operations accomplished with certainty, but the results may be transferred to copperplates, from which any number of copies may be printed without a possibility of error. A very brief notice however of the manner of using it, and of the principles on which it is constructed, can be here given.

In any series of numbers arranged in line or column, if the difference between the first and second, between the second and third, and so on, be taken, there will be formed a line or column of what are called *first differences*; if the difference between the first and second, between the second and third, and so on, of these last numbers be taken, there will be formed a line or column of what are called *second differences*. Proceeding in like manner to form third, fourth, &c., orders of differences, there will at length be found a series of differences which are either constant, or to a great extent are nearly so. Then having any one of the numbers in the first column, and the numbers corresponding to it in the several columns of differences, all the succeeding numbers of the series may be found by mere additions or subtractions, and the latter process may be avoided by using arithmetical complements.

The machine accomplishes these additions by the movements of a number of cylinders having on the convex surface of each the series of numbers 1, 2, 3, 4, 5, 6, 7, 8, 9, 0; and the operations are of two kinds: by the first, the additions are made; and by the second, there is introduced the 1 which should be carried to the *ten's* place every time that the sum of two numbers is greater than 10.

Let it be imagined that there are side by side several vertical axles, on each of which are several cylinders one above another; and that these axles with their cylinders are capable of being turned by wheelwork, so that any one of the ten figures may be made to stand on the face of the machine, and immediately under a fixed index. Let it be further imagined that the figures composing a given number are under the indices in front of the cylinders on the first vertical axis towards the left hand; and the figures composing the several orders of differences in front of the cylinders on the other axis successively towards the right. Then, the general axle of the machine being, by a winch, turned one quarter of a revolution, only the first, third, fifth, &c. axles turn, and every cylinder on each of these axles turns, at the same time, through as many tenths of a revolution as are expressed by the figure in front of the cylinder immediately on its right hand.

There is thus brought to the front of each turning cylinder the unit's figure in the sum of the figure previously in front of that cylinder, and the figure in front of the cylinder on its right. When any of these sums exceed 10, a turn of the general axle through a second quarter revolution causes each of those cylinders, whose number should be increased by the 1 *carried* to describe one-tenth of a revolution, and thus the number in its front becomes greater by 1 than before.

Now, on turning the general axle through a third quarter revolution, the second, fourth, &c. axles only turn, and every cylinder on each turns at the same time through as many tenths of a revolution as are expressed by the figure in front of the cylinder immediately on its right hand; there is thus made, as before, an addition of the figure previously in front of the turning cylinder and the figure on its right. A turn of the general axle through a fourth quarter revolution performs also, as before, the operation of *carrying* where necessary; and now the cylinders on the first axle towards the left present to the front the figures constituting the number which, in the required series, follows the given number. The like operations are to be performed for all the succeeding numbers.

We have it not in our power to do more than give the following very general notion of the mechanism by which these remarkable movements are produced. Behind each column of the cylinders on whose convex surfaces are the nine numerals with zero is a vertical axle, carrying as many pairs of wheels, one above another, as there are cylinders. The upper wheel in each pair acts as a driving wheel to the cylinder, and has besides, on its circumference, teeth like those of an inverted crown wheel, and both wheels are capable of being connected with or disconnected from their common axle; the lower wheel carries on its upper surface an inclined plane, and between the two wheels is a bolt with two pins which project from it, one above and the other below. By the revolution of that wheel, the inclined plane is carried under the lower pin, and thus the upper pin is enabled to enter between two teeth in the crown wheel or to disengage itself from them. Another axle, in a vertical position behind the former, carries projecting bars which, when the axle is turned by the moving power, press upon the bolts and cause the pins to move up or down as above mentioned. This engagement and release of the inverted crown wheel are the means by which the cylinder is made to describe such part of a revolution as is required; and when the cylinder is to remain at rest while those on other axles turn round, an apparatus provided for the purpose removes out of its place the bar which should press against the end of the bolt. The process of *carrying* is accomplished by a bar on the axis of a cylinder, which at a proper time comes against the extremity of a claw; and this then engages itself between the teeth of a ratchet wheel connected with the next cylinder.

In order to transfer to copper-plates the results obtained from the machine, a curvilinear bar of metal is to act on an arm of a lever so as to raise it to ten different heights, corresponding to the ten figures on the surface of each cylinder, and the opposite arm of a lever is to move an arch carrying ten punches having on them in relief, the ten characters, 1, 2, 3, &c. to 0. A bent lever is to press the punch upon the copper-plate and produce the impressions of the figure.

Various circumstances, concerning which there has been much discussion in Parliament and among men of science, have led to the suspension of the construction of this superb machine: a subject of great regret. The portion which has been already executed is now in the library of King's College, London; and it is capable of producing tables of the powers and roots of numbers not extending beyond eight places of figures.

Edmondson's Railway Ticket Machine consists of a series of multiplying wheels, with a stamping and cutting instrument in the interior. There is an index wheel whose disc is engraved with letters and numbers corresponding with those on an inner wheel. When the pasteboard material is introduced, and the machine set in motion by hand, the cards ready printed, numbered, and dated are ejected with great rapidity into a receiving box, ready packed and sorted for delivery; and the machine itself tells with unerring accuracy the number of tickets it has struck off. Machines of this kind are now extensively used at railway stations. Nothing can be more beautiful than the arithmetical accuracy with which this machine delivers and tells off an immense number of tickets in a brief period.

Baranowski's calculating or registering machine, recently introduced, is intended to facilitate many commercial operations. One form of the machine is adapted to the prompt calculation of goods per ton, cwt., or lb., or for the calculation of monies per day, month, or year. By adjusting a slide displaying the given sum, and turning a wheel, the amount per year, or week, or month is given in a marginal slide, which is developed by the operation. Mr. Baranowski has patented various modifications of his machine, adapted for numbering, stamping, and registering.

At the meeting of the British Association in 1840, the Astronomer Royal described a new calculating machine which had been invented by Mr. Fowler, to facilitate the labours of the guardians of a Poor Law district in Devonshire, in calculating the proportions in which the several divisions were to be assessed. The mechanism was much the same as in many other machines of a similar character: but there was a peculiarity in the notation adopted for the special object held in view. Instead of the common *decimal* notation, it had a *ternary* notation; that is, the digits became not tenfold but threefold more valuable in their course from right to left. Thus, in such a notation, 1 and 2 express one and two as in the common system; but 10 express (not ten, but) three, 11 express four, 12 express five, and so on. The relative number of teeth in some of the wheels of the machine would depend on which notational system is employed.

Dr. Roth's Automaton Calculator, introduced about the year 1841, has many modifications suited to the performance of different calculations. The machine for performing addition, subtraction and multiplication consists of a narrow oblong box, with a metal plate on the top, which is divided into nine indexes and semicircular notches. The first six, from left to right, serve for the numbers from hundred thousands to units: the last three are appropriated to shillings, pence, and farthings. Round each index are engraved figures, from 0 to 9; and the semicircular notches contain teeth which correspond with the figures. Under each notch is a circular hole, in which the result of the calculation appears at the end of the operation. In using the instrument, a metal point is inserted in the teeth of such figures in the indexes as are required to be brought into action, and each point is brought down to 0; the result is then read off from the circular opening in which it appears recorded. The interior mechanism consists chiefly of a simple combination of toothed wheels and springs. This machine has been used in some offices to facilitate calculations; and also as a register of the number of strokes or of rotations in machines.

A new calculating or rather numbering machine was invented and patented by Mr. Lewthwaite in 1847; for numbering railway tickets and pawnbrokers tickets, paging books, and similar purposes, and printing numbers in any consecutive or serial form. The mechanism is complicated but ingenious. The chief parts consist of figure-wheels, driving-wheels, and key-stops. The figure-wheel is a wheel with ten teeth, the outer facets or ends of which are stamped or typed with the ten digits from 0 to 9; the driving-wheel is also a wheel with ten teeth, which work between the teeth of the figure-wheel; and the key-stop is a kind of lever, one end of which catches successively in the teeth of the figure driving-wheel. If the machine were only required to number up to 9, comprising only one digit or place of figures, only one figure-wheel would be required; but if two, three, four, or five places of figures be necessary, expressing tens, hundreds, thousands, and tens of thousands, then two, three, four, or five figure-wheels would be required. There are one driving-wheel and one key-stop to each figure-wheel. All the figure-wheels are placed upon one axis, on which they revolve independently of each other; the same may be said of all the driving-wheels, and all the key-stops: each driving-wheel moving its appropriate figure-wheel, and each key-stop being similarly limited. By working a crank handle all the ten facets of the units' figure-wheel come in succession downwards, and stamp or impress their device by a small inking apparatus. When figure 9 is produced, the key-stop catches into the wheel so as to bring the tens' figure-wheel also into action; and two wheels then work together, producing the numbers 10, 11, 12, &c. At every complete revolution of the units' wheel, the tens' wheel makes one tenth of a revolution; at every complete revolution of the tens' wheel, the hundreds' wheel makes one-tenth of a revolution: and so on consecutively. It is obviously a sort of clock-work mechanism, with figures at the ends of the cogs capable of being brought into such a position as to print their results upon paper.

In 1849 a Calculating Machine was introduced before the British Association, invented by M. Slovinski, a Pole. It consists of a thin box covered by a metal plate, in which are ten circular apertures; the digits from 0 to 9 are marked near these holes, and toothed wheels are placed behind them. The upper part of the instrument is used for addition and the lower for subtraction; and the processes are performed by causing a rotation of the wheels which correspond to the digits to be added or subtracted. The multiplication instrument consists of a shallow rectangular box, containing cylinders which are made to revolve by knobs that protrude through the box. The cylinders have printed tables of figures on their circumference, and there are also index figures which appear through small holes over the axes of the cylinders. Besides these index holes there are nine other rows of holes, eight in a row, at which appear the results of the multiplication. The instrument can perform all sums up to millions multiplied by millions.

A principle of numerical reckoning is adopted in Whiffen's Registering machine, patented in 1850. It consists of a dial-plate and a system of wheel-work, to be attached to the trap-door of ship's coal weighing machines. The object is to determine the number of times that the door is opened for the discharge of coals. The same object, it is conceived, may be attained in respect to the filling of grain measures; but there is nothing essentially new in this: it is but an application of the principle of the WEIGHING MACHINE.

A remarkable apparatus for registering votes by ballot is described under VOTING MACHINE.

CALCUTTA, the seat of the supreme government of Great Britain in the East Indies, possesses great advantages for inland navigation. All kinds of foreign produce are transported on the Ganges and its affluents with great facility to the north-western parts of Hindustan over a distance of at least 1,000 miles, while the productions of the interior are received at Calcutta by the same channel. Operations have lately commenced for the construction of a railroad from Calcutta to Delhi, a distance of more than 1,000 miles, of which so much as can be constructed for 3,000,000*l*. is to be proceeded with forthwith.

The chief articles of export from Calcutta are indigo, opium, sugar, raw silk, and silk piece-goods, saltpetre, rice, hides, cotton, and cotton piece-goods. The chief articles of import are British cotton manufactures and cotton twist, bullion, copper, tin, lead, zinc, iron, and other metals; woollens, wines and spirits; hardware and cutlery; jewellery, watches, &c.; coffee, tea, books, and stationery.

The present system of communication between London and Calcutta by steam-vessels (the 'overland route') was established in 1845; but it is hoped that the time is not far distant when Calcutta will also have communication with China and with the Australian colonies. The foreign commerce of Calcutta has been already noticed under BENGAL.

CALENDERING, in the manufacturing districts, is a general name applied to the processes of smoothing, dressing, and glazing cotton and linen goods; the object being either to prepare them for the operations of the calico-printer, or to impart the last finish to the goods before they are folded and packed for the market. The earlier calenders, or calendering machines, closely resembled a common mangle in their action, but were very large and heavy, and worked by a horse-wheel, or other sufficient power; but the process was greatly improved by the invention of a machine in which the pressure is produced between cylinders, instead of between cylinders and flat surfaces, and in which, consequently, the alternating motion is got rid of, and, also, it is easier to give a uniform and equal pressure. The rollers or cylinders were formerly made of wood; they are now usually made either of paper or of cast-iron. The paper cylinders are formed by packing a great number of circular pieces of stout pasteboard upon an iron axis, and compressing them very tightly by means of iron bolts passed through them, acting upon circular end-plates of cast-iron. The surface is brought to a perfectly even and polished state by turning in a lathe. Iron rollers are made hollow, and, when necessary, heated from the inside. Where a glazed or polished surface is required on the goods to be calendered, mechanism is employed to cause two adjacent rollers to revolve with different velocities, so as to produce a rubbing action.

CALF. The rearing and fattening of calves is an important part of rural economy. In dairy districts the milk is so valuable, that the calves are got rid of as early as possible, and are purchased by the calf-dealers, who fatten them and prepare them for sale to the butcher. Calves should be fat by eight or nine weeks old; it is seldom advisable to keep them above twelve weeks, as they then consume a greater quantity of milk than can be afforded. In some countries calves are killed when only a few days old; the flesh is then soft and tasteless. In France and Switzerland no calf is allowed to be killed for sale under the age of ten days. Calves intended to be reared for grazing or the dairy are suckled for three or four days, then brought up by the pail, and gradually educted from their milk diet to one of a vegetable nature. About 30,000 calves are sold annually at Smithfield. About 14,000 calves were imported from foreign countries in 1849; this import commenced in 1842. Calf-skins form the material for one of the most valuable kinds of leather.

CALIBRE, CALIPER, or CALLIPER. The first of these words is French, and was a technical term signifying the internal diameter or *bore* of any piece of ordnance. In England it has come to signify generally the diameter of any round substance. Caliper compasses, or callipers, are compasses intended to measure the calibre or diameter of round bodies, and are formed with curved legs.

CALICO. [COTTON.]

CALICUT, a sea-port town in Hindustan, is worthy of notice as exemplifying a remarkable fact in the history of manufactures. It used to be an extensive cotton manufacturing town: our word *calico* being derived from it; but, notwithstanding Indian cotton and Hindoo labour being so cheap, cotton goods are now mostly imported. The present exports consist principally of cocoa-nuts, betel-nuts, pepper, ginger, turmeric, teak-wood, sandal-wood, cardamoms, and wax.

CALIFORNIA. There is, perhaps, no parallel in the history of nations to the rapid growth of a community in California. That which was almost a desert country four or five years ago is now a busy mart of commerce and mining.

The whole region of California comprises the wide stretch of Pacific coast from Oregon in the north to Mexico in the south; but that portion which now attracts commercial attention is the river district, whereof the outlet is at San Francisco, in 38° N. lat., 122° W. long. Here, about the time that California was assigned by treaty from Mexico to the United States, gold was first discovered—unless, indeed, as is supposed, the Jesuits were aware of its existence there some generations back. The gold is so loosely mixed up with sand and sediment in the bed and the banks of the Sacramento and other rivers, that the grains and small particles are without difficulty separated from the impurities. For a short time the secret was retained by a few; but no sooner did the news spread abroad than a gold mania sprang up. The Mexicans, from the hitherto insignificant town of St. Francisco, the native Indians of the country, and the hardy trappers and backwoodsmen from the United States, all rushed to seize the golden treasure. After a time the Sandwich Islanders heard the news, and steered over the Pacific to get a share of the riches. Vessels came to St. Francisco from different ports; and the seamen, abandoning their vessels to the mercy of chance, ran off to the 'diggings' and became gold-hunters. Soon the tidings reached the United States, and parties and companies set forth to El Dorado, the golden land. Some took the perilous inland route across the Rocky Mountains; some adopted the tedious sail round Cape Horn; but the majority have availed themselves of the Panama route. The tens of thousands who thus went, having no other object than to get gold, had neither means nor inclination to grow their own food nor to manufacture their own necessaries; and hence arose a field of enterprise which the merchants of England and of the United States did not neglect. Valuable cargoes were transmited to St. Francisco to be there sold in exchange for the gold-dust; and as such transactions could not be carried on without some kind of commercial machinery, St. Francisco speedily put on those features which distinguish a busy port.

So rapid have been these transactions that they have scarcely yet been narrated in an authentic form. It would not be safe to say how much gold-dust has left California, nor how many adventurers have arrived there, for both have been exaggerated. St. Francisco has been nearly destroyed by fire three or four times during its brief existence; yet it rises from the ashes, after each conflagration, with increased vigour and importance. We may simply jot down two or three facts which serve to illustrate the present position of this remarkable place.

During one week in 1850 gold-dust to the value of three million dollars was shipped and exported from St. Francisco. In August of the same year the monthly shipment was about 8,000,000 dollars, of which gold-dust to the value of 3,000,000 dollars was transmitted to England, the rest being consigned chiefly to the United States. On September 15, 1850, there were in that port no less than 684 vessels of 181,021 tons, belonging to twenty-one different nations; 496 vessels belonged to the United States, 86 to England, all other countries much smaller numbers; some of the vessels, small in size, had crossed the whole breadth of the Pacific from Australia and New Zealand, with the view of exchanging their produce for gold-dust. In the first two weeks of October, in the same year, 94 vessels arrived at St. Francisco, besides the mail steamers which ply between that town and Panama, and besides 10 other steamers which now ply between St. Francisco and the smaller Californian ports. Between 40,000 and 50,000 letters now cross the isthmus of Panama every month *en route* from the Atlantic nations to California, and an equal number in the opposite direction.

As might reasonably be expected under such circumstances, recklessness and mad speculation have done much injury at California; but the United States government has shown energy in establishing steady and useful laws and institutions in its newly-acquired territory; and, whatever may be said of the *Industry* of all nations, the *Commerce* of all nations is likely to be instructively illustrated at California.

CALLAO, a small sea-port town in Peru, derives all its commercial importance from being the port for Lima, which is seven miles distant. The Peruvian ships in 1840 amounted to 57 (6637 tons); in the same year the custom duties on British goods, chiefly cottons and linens, amounted to 240,000*l.*; and the total value of British manufactures sent to Peru through Callao and Valparaiso was 1,230,000*l.* The exports from Callao consist of bark, bullion, specie, copper in ore and in bars, raw cotton, hides, &c. The value of the exports to Europe and the United States in 1840 was 948,346*l.*, being an increase of 315,476*l.* on the preceding year. There has since been a small annual increase in these quantities.

CALOMEL. [Mercury.]

CALOPHYLLUM is the name of a genus of trees from which much useful oil is procured. The *Calophyllum Inophyllum* is a native of the East Indies, and often attains a height of 90 or 100 feet. It has large handsome leaves like those of a water-lily, snow-white fragrant flowers, and a fruit about the size of a walnut. The nuts afford a fixed oil, which is expressed and used for burning in lamps. Another species, the *Calaba-tree*, attains a height of 60 feet, and is a native of the Caribee Islands. It has white sweet-scented flowers, and a green fruit something like the Cornelian cherry, which contains a white solid kernel. An oil is expressed from the seed for domestic uses and for burning in lamps. The timber is used for various purposes, especially for staves and cask-headings.

CALOTYPE. The patent for Mr. Fox Talbot's Calotype, obtained in 1841, contained specifications relating to many departments of photographic operation; but the proper calotypic process is what we are here concerned with. The operation comprises three stages—to prepare the paper; to produce the negative picture; and to produce the positive picture. The best and smoothest writing-paper is washed on one side with a camel-hair pencil dipped in a solution of 100 grains of crystallised nitrate of silver in six ounces of distilled water. The paper is dried slowly, and then dipped for a minute or two in a solution of 500 grains of iodide of potassium in a pint of water; it is then dipped in water and dried. Immediately before using, this paper is washed on the prepared side with a solution of 100 grains of nitrate of silver in two ounces of distilled water, combined with one-fourth of its volume of acetic acid, and an equal quantity of tincture of galls or of a saturated solution of crystallised gallic acid. The paper is dried a third time, and is then ready for use. In taking the calotype picture, the paper is placed in a camera obscura, where it speedily receives the image, which sometimes requires to be brought out by a wash of gallo-nitrate of silver. To fix the image, the paper is dipped into water, partly dried with blotting-paper, and washed with a solution of 100 grains of bromide of potassium in 8 or 10 ounces of water, after which it is again washed and dried. The image or picture thus produced is a *negative* one, the lights and darks being reversed. To produce a *positive* picture from this, a second sheet of calotype paper, or of common photographic paper, is placed in contact with the picture; a board is placed beneath, and a plate of glass above them, and all are screwed closely together. On placing them in the sunshine for some time, a picture with the lights and shadows in their natural position is produced on the second paper; and this duplicate is to be fixed in the same manner as the original picture. Many calotype positive pictures may be taken from one negative picture.

In another method, Mr. Talbot produces a positive calotype at once, without the intervention of a negative one. A sheet of calotype paper is exposed to the daylight until its surface is slightly browned. It is then dipped into a solution of iodide of potassium; on being taken out of this solution the paper is dipped into water and partially dried. It is next placed in the camera, where, in the course of five or ten minutes, the image becomes impressed upon it. The paper, when removed from the camera, is washed with gallo-nitrate of silver, and warmed. A positive picture then makes its appearance on the surface.

CALUMET, the name given by the North American Indians to a pipe for smoking tobacco. The calumet, or pipe of peace, is a large tobacco pipe, with a bowl of polished marble, and a stem two feet and a half long, made of strong reed, adorned with feathers and locks of women's hair. When it is used in treaties and embassies, the Indians fill the calumet with the best tobacco, and, presenting it to those with whom they have concluded any great affair, smoke out of it after them.

CALVADOS, a department in France, which formerly constituted part of Normandy, is a great cider district, the annual produce being about 30,000,000 gallons. The best kind is that made in the Auge district; it will keep for years and contains a large proportion of alcohol. Melons, haricots, onions, &c., are extensively cultivated. The department contains about 1,000 wind and water mills, 150 foundries and furnaces, and about as many factories. Building stone, marble, slate, brick, potter's clay, and iron, are found. Marl abounds in the arrondissement of Lisieux and Pont-l'Evêque, and is used for manure. Coal mines are worked at Littry, in which several steam engines are employed.

The chief industrial products of the department are cotton and woollen yarn, fine and coarse woollen cloths, linen, flannel, blankets, shawls, calicoes, lace, porcelain and cutlery. Throughout the department the manufacture of lace alone gives employment to 50,000 persons, and the value of the lace annually exported amounts to many millions of francs. The department contains several paper-mills, sugar refineries, tanneries, oil-mills, and establishments for the manufacture of chemical products and bleaching linen. The commerce consists of its industrial products, together with horses, fat cattle, butter, cheese, poultry, cider, honey, spirits distilled from cider, clover seed, hemp, wood, oil, &c. The imports are iron, wool, raw cotton, hides, and colonial produce. Great quantities of lobsters, oysters, and other fish, are taken along the coast and conveyed to the markets of Paris and of the interior.

CAMBOGE, or GAMBOGE. This gum-resin was introduced into Europe by Clusius about 1603. From the bruised leaves and young branches of *Stalagmites cambogioides* flows a yellow juice, which is received in cocoa-nut shells or earthen vessels; it is then allowed to thicken, and afterwards formed into rolls; this is the finest sort called the *Pipe Camboge* of Siam. A portion is formed into round cakes, which are either entire or have a hole in the centre; this is the *Cake Camboge* of Siam.

At the ordinary temperature of the air, camboge, from whatever source obtained, has little smell, but when heated gives out a very peculiar one. Taken into the mouth it has scarcely any perceptible taste, but upon being chewed for some time it causes a sharp and somewhat acrid feeling, ending in a sweet sensation, accompanied with dryness in the mouth. It excites afterwards a flow of saliva, which is coloured yellow. It is almost entirely soluble in alcohol, and is not precipitated from solution by the addition of water. With water it forms an emulsion, in which the resin is kept suspended by the gum. It is soluble in the alkalies. The resin, which forms three-fourths of its weight, may be considered its active principle.

Camboge is much used in medicine, especially in quack medicines; but it is more extensively used as a pigment.

CAMBRIC. This is one of the numerous varieties of flax or linen manufactures, which derived its name from having been first made at Cambray. It bears much the same relation to linen that muslin does to calico, being a very fine and thin fabric. Scotch cambric, now largely manufactured, is a kind of imitation cambric, made from fine hard-twisted cotton. The French material called *batiste* is a sort of Scotch cambric, to which dyes and printed colours are applied.

In 1848 about 33,000 pieces of French cambric and lawn were imported. In 1849 the quantity sank to 29,000 pieces.

CAMBRIDGE is so much more closely

associated with education than with trade, that we can have little to say concerning it in this place. It has however a considerable trade in coals and grain; and a large quantity of butter is conveyed from Norfolk and the Isle of Ely to London, where it obtains the name of Cambridge butter.

CAMBRIDGESHIRE is so purely an agricultural county (except in relation to the straw-plait manufacture, and one or two others), that we need merely say a few words concerning its fens. When these fens are drained [BEDFORD LEVEL], the first operation is to pare, by means of a paring plough, the surface on which coarse grass and sedge are growing in a matted state. The sods are then burnt, and reduced to a carbonised mass, which, when cool, is spread over the ground. This is immediately ploughed in, and the land is sown with cole-seed or rape, of which an abundant crop is invariably produced. The cole is fed off with sheep, the land ploughed once, and oats are sown, which produce astonishing crops; after which the land is available for the rotation culture. Rape-cake is much used as manure. The uncultivated fens yield turf, reeds, and osiers.

CAMEL. The camel is an important adjunct to trade and commerce in tropical sandy regions. The organization of this animal proves its adaptation for the arid deserts over which it is destined to travel. The pads, or sole-cushions of the spreading feet, divided into two toes without being externally separated, which buoy up, as it were, the whole bulk with their expansive elasticity from sinking in the sand, on which the animal advances with silent step—the nostrils so formed that the animal can close them at will, so as to exclude the drift sand and the parching simoom—the beetling brow, and long lashes which fringe the upper lid, so as to screen the eyes from the glare of the sun—the cleft prehensile upper lip, and the powerful upper incisor teeth, for browsing on the dry tough prickly shrubs of the desert—the hunch acting as a reservoir of nutriment against a time of long abstinence—and the assemblage of water tanks in the stomach—these are characteristics without which the 'ship of the desert' could not render his invaluable services to man.

The Bactrian, or *two-humped* camel, occurs throughout Central Asia; it is the patient, laborious, and willing slave of the Turcomans, travelling over sandy deserts, and administering to the wants of a wandering people. The Arabian, or *single-humped* camel, or dromedary, is spread through Egypt, Arabia, Syria, North Africa, Persia, India, &c., and its history is interwoven with that of the patriarchs of old, nor is it now less important than in those early days. Caravans of camels still traverse the desert, conveying merchandise. The load of a camel is from 500 to 600 lbs., and it will move at the rate of nearly 3 miles an hour, regularly as clock-work, day after day, for eight hours daily. It lies down, resting on the callosities of its breast and limbs, to be loaded and unloaded. In the oriental caravans some of the animals are loaded with water skins, some with merchandise, others carry the food and necessaries of the pilgrims and their own provender, and others are mounted by riders.

The camel is not only serviceable as a beast of burden; its milk and flesh are both in requisition, especially the former. Of its hair the Arab weaves clothing, and even tents; his belt and sandals are the produce of its hide; and the dung affords him fuel. From the soot, sublimated in closed vessels, is procured sal ammoniac, formerly imported into this country from Egypt. Camel's hair is imported into this country for the manufacture of pencils for the painter; that from Persia is the best. There are three qualities, black, red, and gray; the black is most valuable, next the red; the gray is very inferior.

CAMEO, or CAMAIEU, is a gem worked in *rilievo*. The art of engraving on stone is of high antiquity; but it was for the most part confined to *intaglio*, or indenting. It has been supposed that the Etruscans had the art of engraving hard stones before it was known to the Greeks; many engraved stones, however, that are called Etruscan are doubtless early Greek, as may be inferred from their subjects.

The age of Augustus is remarkable for the excellence of the gem-engravers who were then living. One of the finest camei preserved in the collections of Europe is the Apotheósis of Augustus, in the collection at Vienna. In the French collection, the sardonyx of Tiberius is one of the best known. We possess in this country some camei of first-rate excellence, but they are chiefly in private collections.

The workers in cameo not only exercised their skill in the cutting or engraving, but also in so arranging their subject and the composition of its details as to make the different colours or zones of the stones answer for parts of the design. The ancients were so partial to this variously coloured work, that they even imitated the material in glass; and we possess in this country one of the most beautiful specimens of their ability in the Barberini, or Portland Vase, now in the British Museum.

At the decline of the Roman Empire, gem-engraving fell with the other arts; and it was not till a late period that the taste and munificence of the Florentine family of Medici caused its revival in Italy. It was much encouraged in the fifteenth century, and the sixteenth century can also boast of several very distinguished artists in this class. In the succeeding century there was a considerable falling off, but in the eighteenth the art again rose.

Rome is now the chief seat of the art of cameo-cutting. There are two kinds: those cut in *pietra dura*, or hard stone, and those cut in shell. The stones most prized for this purpose are oriental onyx and sardonyx—provided they have at least two different colours in parallel layers. The value of the stone is greatly increased if it has four or five differently coloured parallel layers, provided that the layers are so thin as to assist in marking the device of the cameo. For example, a specimen of stone which had four parallel layers might be useful for a cameo of Minerva; where the ground would be (say) dark gray, the face light, the bust and helmet black, and the crest over the helmet brown or gray. All such camei are wrought by a lapidary's lathe with pointed instruments of steel, and by means of diamond dust. Shell cameos are cut from large shells found on the African and Brazilian coasts, and generally show two layers, one white, and the other either pale coffee colour or deep reddish orange. The subject is cut with small steel chisels out of the white portion of the shell. The gem camei are far more costly than those made of shells.

At the Mediæval Exhibition of 1850, very beautiful specimens of the cameo were exhibited in sardonyx and blood stone.

Camei to the value of 6,502*l.* were imported from France in 1847.

CA'MERA LU'CIDA and CAMERA OBSCU'RA (*light and dark chambers*) are names given to two methods, very like in principle, of throwing images of external objects upon a plane or curved surface, for the purpose of drawing or amusement.

The *Camera Obscura* now in use has, occasionally, the form of a box. In front is a sliding tube, carrying a convex lens, through which the light from distant objects passes to a mirror at the opposite extremity of the box: the mirror is inclined to the horizon at an angle of 45 degrees, and from thence the light is reflected upwards to a glass plate in a horizontal position. The rays in the pencils converge at the upper surface of this plate, which, on that surface only, is ground rough, and thus the images of distant objects are visible upon it, a shade over the plate preventing the direct light from interfering with them.

A camera obscura for exhibition is generally made in a room with a conical roof and an aperture at the top. Above this aperture is a revolving plane mirror inclined at 45°, and reflecting pencils downwards. A convex lens causes these pencils to converge upon a surface of plaster of Paris, properly curved. The mirror revolves about a vertical axis, thus allowing all the compass points of a landscape to be successively thrown on the surface.

Portable camera obscuras are often made in a similar manner, the mirror and lens being in a sliding case at the top of a pyramidal box, and the image being received on paper laid at the bottom. Apertures on one side of the box allow the spectator to see the image and introduce a hand for the purpose of drawing on the paper.

A camera obscura is an indispensable aid in most forms of photographic operation.

The *Camera Lucida* was invented by Dr. Wollaston. It consists of a metal stand supporting a glass prism, of which one angle is 135°. The action of the instrument is such, that when rays of light fall horizontally on one side of the prism, they suffer reflection within the glass, and are thrown upwards to the eye through an opening in a plate which excludes all except the end of the prism, and a part of a sheet of paper or other flat surface placed beneath the prism. Hence the image of an object is thrown towards the visible part of the paper, and, the eye viewing both the image and the sheet of paper (with different parts of the pupil, however, which creates a difficulty in using this instrument), the observer is enabled to trace the object upon the paper.

The image of the distant object must be made to coincide with that of the paper; and, for this purpose, since, except when the object is very remote, the rays in the pencil are in a divergent state, a convex lens is interposed between the prism and the paper.

CAMP, ROMAN. In a Roman camp the standard was fixed in the centre, and around this, within a space of 200 feet each way, was the prætorium or place of the general's quarters, on one side of which was the forum, and on the other the space allotted to the stores of the army, with the quarters of the Quæstor, or officer who had charge of the military chest. Further, towards the right and left were the cavalry and infantry, forming the general's body-guard, and the volunteers in his service. This line, which in length may be estimated at 1650 feet, constituted the breadth of the camp. In front of the line were the tents of the legionary tribunes and of those officers among the allies who had corresponding rank. Before the tribunes' tents was the principal street, 100 feet wide, stretching across the camp; and beyond this, extending about 1050 feet towards the front, were the quarters of the soldiers. These were divided into two parts by a street 50 feet wide, which ran from the prætorium to the head of the camp. The streets divided the various bodies of soldiers.

Such was the order of encampment for a consular army, consisting of two legions besides the allies; its whole depth might be about 1700 feet; and there was round the encampment a clear interval 200 feet broad, between the tents and the entrenchments. These consisted of a rampart of earth and stones, and a ditch, through which were four gates or entrances: the Prætorian gate, in front of the camp, opposite the Prætorium; the Decuman gate, at the back of the camp, and a gate at each end of the Principia or principal street.

CAMPANI'LE, an Italian term signifying a tower for bells. The word is derived from *campána*, 'a bell.' Many of the Italian churches have these towers or campanili separated from the body of the church. Among the most remarkable are those of Cremona, Florence, Ravenna, Padua, Bologna, and Pisa. The leaning tower of Pisa is a campanile; it is 150 feet high, and 13 feet out of the perpendicular. The campanile of Cremona is the highest in Italy, having an elevation of 395 feet. The campanile of Florence, which is 267 feet high, was constructed by Giotto in 1324, and is considered the most elegant campanile in Italy; the façade of the tower is in the Gothic style, mixed with somewhat of the Italian taste in architecture, which soon after prevailed over the Gothic. The cathedral at Seville has a fine campanile 350 feet high, which was built in 1568 by Guever the Moor.

CAMPA'NULA. Many plants belonging to this genus are usefully applied. The *campanula edúlis* is a native of Arabia Felix; its root is thick and sapid, and contains a considerable quantity of starch; it is on this account frequently eaten by children, as are the roots of many other species. Of the *campanula rotundifolia*, or *blue-bell*, the juice of the flowers makes a very good blue ink, and when mixed with alum a green one. The roots of this species also may be eaten. The *campanula rapunculus* is much cultivated in France and Italy, and sometimes in Britain, for the sake of the roots, which are boiled tender, and eaten hot with sauce, or cold with vinegar and pepper.

CAMPHINE LAMPS. Camphine is very pure spirit of turpentine, obtained by the distillation of common turpentine. Turpentine is very cheap in the United States, and camphine is there much used for lighting; and when the duty on turpentine was reduced in England a few years ago, the use of camphine became familiarized among us—one of the many proofs how much influence fiscal laws have upon manufactures.

The light produced from camphine is very pure and brilliant; and the modes of applying the liquid to this purpose have given rise to various forms of lamp which are now familiar; such as the 'Vesta,' the 'Imperial,' the 'Victoria,' the 'Gem,' the 'Paragon,' and many others. All lamp-oils contain some oxygen, which neutralizes a part of the hydrogen and carbon; and also some oxide or other substance which damps the brilliancy of the flame; whereas rectified camphine, being composed almost wholly of hydrogen and carbon, contains nothing but what is susceptible of combustion. The best camphine is obtained, as stated, from turpentine; but tar and naphtha, if subjected to careful distillation and rectification, will yield very fair camphine.

In using camphine for lamps, certain precautions are necessary. Camphine is so extremely inflammable, that the arrangements of a common oil-lamp would not be available without danger of accident. All the camphine lamps present in common a reservoir, generally of glass, placed between the supporting pillar and the burner; the spirit is contained in this reservoir, and a cotton wick dips down into it. The chief points in which the various camphine lamps differ are in the arrangement for admitting air to the flame. In Young's 'Vesta' lamp, the cotton wick hangs down from the burner into the camphine, so as to supply itself by capillary attraction, without the intervention of any metallic or heat-conducting substance.

As a question of art-manufactures, many camphine lamps are now made of very elegant forms. The last Birmingham Exposition was rich in specimens; and we may reasonably expect that the Great Exhibition of 1851 will not be deficient in this respect.

A very elegant application has been made of the gas produced from camphine. The gas can be made with a small apparatus, and with little difficulty; and the jet which it produces is very pure and brilliant. The camphine is heated in a retort set in a small furnace; and the gas, escaping from the retort, is purified by passing through certain liquids. This gas has been found useful for lighting railway stations and other buildings, too far distant from ordinary gas-works.

CAMPHOR is the stearopten (or one of the principles arising from the separation of the volatile oil) of two trees—the one *Cinnamomum camphora*, a native of Japan, China, and Cochin China; the other, *Dipterocarpus camphora*, a native of Borneo and Sumatra. From these it is procured by different processes. It exists in every part—root, stem, branches, and leaves—of the Cinnamomum camphora, which is chopped into pieces sufficiently small to be thrown into iron vessels: these vessels are afterwards covered with earthern hoods, in which are placed rice-straw and rushes, heat being subsequently gradually applied. The camphor is volatilised, and afterwards condenses on the straws, rushes, &c. This, after being purified from the intermixture of straws, is found in commerce under the name of crude camphor.

From the Dipterocarpus camphora it is not procured by distillation, but exists in a solid form in the stem of the tree. In that part of the stem which should be occupied by the pith it is found along with camphor-oil, and on the trunk being split open the camphor is found in the centre, in pieces about a foot long, which is much prized and used in the East, but is not sent to Europe.

Camphor is an organic substance of a peculiar kind, representing the volatile oils in a solid state. It is so volatile, that on exposure to the air it is entirely volatilised, and leaves no residuum. It is insoluble in water, but is easily dissolved in spirit, is inflammable, and has an aromatic smell and taste. It is much employed in medicine.

Two substances, called *camphor oil* and *camphoric acid*, are obtained from camphor: they are not much employed.

CAMWOOD, is a red wood, the colouring matter of which is similar to that of Nicaragua or peach wood. It is used in dyeing, and also in cabinet work. It is brought chiefly from Sierra Leone.

CANADA. This large country, with its magnificent lakes, cannot fail to rise steadily in commercial importance. The mineral resources are immense, but till very recently they have been almost wholly neglected. Marbles and serpentine are quite common. Plumbago, ores of antimony, lead, iron, and copper are frequently met with. The mountains north of the Saguenay abound in iron to such an extent as to influence the mariner's compass. The iron mines of St. Maurice have long been celebrated for the excellence of their yield, and metal not at all inferior is cheaply produced at Charlotteville near Lake Erie, and at the Marmora works about 32 miles N. of the Bay of Quinté. The dreary wastes northward of Lake Superior contain stores of copper, perhaps unsurpassed any where in the world. At the Coppermine river 300 miles from the Sault de St. Marie the metal occurs in great masses in a pure state. Gold, silver, and tin have also been discovered in the same region. The northern and western shores of Ontario abound in salt springs, some of which (Stony Creek and St. Catherine's) are very productive. The north shore of Lake Erie exhibits immense beds of gypsum which are quarried for agricultural purposes.

Copper mining is now being prosecuted with great energy on the banks of Lake Superior. If the accounts recently received should prove correct, Canada will far excel every other part of the world in the richness of the copper ore; indeed it seems as if the produce should scarcely be termed ore: it is almost pure native copper.

The variety of trees found in the vast Canadian forests is astonishing, and it is supposed that many kinds still remain unknown. Of all these none is more beautiful and useful than the maple, the adopted emblem of Canadian nationality. Its timber is valuable for many purposes, and large quantities of excellent sugar are made from its sap. The other forest trees most prevalent are beech, birch, elm, bass, ash, oak, pine, hickory, butternut, balsam, hazel, hemlock, cherry, cedar, cypress, fir, poplar, sycamore, whitewood, willow, and spruce. Timber and ashes, the raw produce of the forests, constitute the chief exports of the province. An immense quantity of oak and pine is annually sent down to Montreal and Quebec. The American ashes contain a larger proportion of pure potash than those of Dantzic or Russia.

The total breadth of land under culture in Lower Canada in 1844 was 2,802,317 acres. The number of inhabited houses in Lower Canada in the same year was 108,794; the number building 1652; vacant 4115. The following particulars, given in the returns of that year, throw some further light upon the habits and occupations of the people:—Lbs. of maple sugar 2,272,457; number of taverns, 1052; stores where spirituous liquors are sold, 808; grist mills, 422; oatmeal mills, 108; barley mills, 45; saw mills, 911; oil mills, 14; fulling mills, 153; carding mills, 169; threshing mills, 469; paper mills, 8; iron works, 99; triphammers, 18; nail factories, 6; distilleries, 36; breweries, 30; tanneries, 335; pot and pearl ash factories, 540; other factories,

86. There were in Lower Canada in 1844, 469,851 cattle, 146,729 horses, 602,821 sheep, and 197,985 swine.

In Upper Canada in 1848 the number of acres occupied was 8,613,591. The lands returned as under cultivation were 1,780,152 acres arable, and 766,768 pasture, or 2,546,920 in all. The crops of Upper Canada in 1847 were—Wheat, 7,558,773 bushels, (an increase of more than 50 per cent. in five years); barley, rye, and buckwheat, 1,394,593; oats, 7,055,730; maize, 1,137,555; potatoes, 4,751,331; peas, 1,753,846. In 1848 there were in Upper Canada 565,845 neat cattle, 151,389 horses, 484,241 hogs, 833,807 sheep. The average annual yield of maple sugar in Upper Canada is 4,140,667 lbs., which is very nearly 6 lbs. for each inhabitant, no portion of this produce being exported. There were sent to market in 1848—butter, 3,380,406 lbs.; cheese, 668,357 lbs.; beef or pork, 99,231 barrels. In the census returns of 1848 are enumerated 553 grist mills, 96 oat and barley mills, 1584 saw mills, 239 fulling mills, 138 distilleries, 100 breweries, 354 tanneries, 1,200 asheries, 67 woollen factories, 10 shingle factories, 105 foundries.

From the United Kingdom Canada receives coals, metals, cordage, East India produce, and the various kinds of British manufactures; from the British West Indies, sugar, molasses, coffee, rum, and hard woods; from the United States, beef and pork, biscuit, rice, and tobacco. The exports of Canada are—to the United Kingdom, pot and pearl ashes, wheat and flour, and timber; to the West Indies, beef and pork, beer, grain, and flour; to the United States, forest produce, wheat, flour, butter, wool, live stock, &c. The total exports of the colony in 1847 amounted to 2,612,852*l*.

The exports of British and Irish produce and manufactures to Canada, in 1849, amounted to the large sum of 1,324,931*l*. It may be interesting to note some of the chief items:—

Apparel	£111,772.
Cotton goods	357,626.
Hardware and cutlery ...	64,470.
Iron and steel	208,391.
Linen goods	52,527.
Silk goods	50,624.
Woollen goods	219,630.

The commercial prosperity of Canada will be greatly increased by the Great Western Railway, now being constructed from Detroit to Niagara: a portion of 75 miles, from Hamilton to London, is under contract; and the works have been pushed forward with great energy during 1850.

In no part of our colonies has the Great Exhibition of 1851 been welcomed with more heartiness than in Canada. As a sort of test of their manufacturing ability, the colonists held an Industrial Exhibition of their own at Montreal, in October 1850, at which the manufactures filled two vast rooms. Hardware, cutlery, cottons, woollens, linens, silks, earthenware, and other goods of Canadian manufacture; corn, beef, pork, butter, cheese, maple-sugar, honey, hams, of Canadian growth; a veneer of bird's-eye maple, 100 feet long, sawn from a single log; soft and beautiful leather made from porpoise-skins; clear and bright oil obtained from the same animal—these were some of the specimens in the Montreal Exhibition. Mr. Logan, a Canadian geologist, has been employed to classify specimens of all the principal minerals found in that country. Household furniture, of Canadian forest-wood, is to be transmitted to London. During the last week in 1850 the ship *Pearl* arrived in London, bringing the first consignment of Canadian specimens for the Great Exhibition, in 107 packages.

CANAL. Ancient Egypt was intersected with canals, which were used both for navigation and irrigation; and in China they have been in use from before the Christian æra. The first made in Europe appears to have been that cut by Xerxes across the low isthmus of Athos. The Romans made canals in Italy and in the Low Countries, about the outlets of the Rhine, and probably also in Britain. In modern Europe canal making commenced in Lombardy between the 11th and 13th centuries, and in Holland, where they may be compared for number with the public roads of this country, in the 12th century.

The origin of canal navigation in this country dates from 1755, when an act of parliament was passed for constructing a canal about 11 miles long from the mouth of Sankey-brook, on the Mersey, to Gerrard's Bridge and St. Helen's. The next works of this kind are noticed under BRIDGEWATER, DUKE OF; and BRINDLEY.

During the remainder of the 18th and the earlier years of the 19th centuries, the construction of navigable canals was carried on with vigour, until they were made in England alone to an aggregate length of more than 2200 miles. In conjunction with new canals, many rivers have been artificially rendered navigable, so that it has been asserted that no spot in England, south of Durham, is more than 15 miles distant from water communication. The introduction and rapid extension of railways has almost entirely put a stop to the construction of canals, and in several instances canals either have been, or are about to be, drained and converted into railways; but it is by no means indisputably proved that the newer and more rapid mode of transit can compete with canals in the transit of heavy goods, especially as competition has led to a very great reduction in canal charges, and to improved modes of conducting the carrying trade.

In cutting a canal where the soil consists of sand, gravel, loose rock, or other matter through which the water will percolate, the floor and sides of the canal must be covered with an impervious lining, called *puddling*, which generally consists of light loam and coarse sand or fine gravel, well mixed with water, and applied, in a semi-fluid state, in three or more successive strata, each carefully worked into the preceding, to the thickness of about three feet. The puddling is then covered with common soil to the depth of 18 or 24 inches. Strong clay is not suitable for puddling, on account of its tendency to shrink and crack, nor is any soil containing roots or other organic matter which would decay and leave cavities. As a further security against the escape of water, *mud* or *puddle-ditches* or *gutters* are sometimes formed along the sides of the canal. They are ditches about three feet wide, dug perpendicularly to a depth below the bottom of the canal, and gradually filled with puddling stuff to a few inches above the top water-line. When the banks are raised above the natural level, if the soil be of a porous nature, their stability will be aided by covering them with turf.

Canals are supplied with water from springs and rivulets, and reservoirs are occasionally necessary. Steam-engines may in some cases be indispensable for raising water to supply these reservoirs; and many arrangements are necessary with the owners of mills and others affected by any interference with the waters from which a supply may be taken. Puddling, embanking, and other engineering operations may be needed in improving the streams adopted as feeders; and in some cases brick culverts or iron pipes may have to be used to conduct the supply. Where the feeders have to be conveyed across a valley or another stream, cast-iron pipes may be found very advantageous.

When the canal passes through an uneven country it must frequently be conducted in a very tortuous course to maintain the level; and deep cuttings, tunnels, embankments and arched or iron aqueducts must be introduced where the level of the canal is unavoidably much below or above the natural surface. Canal tunnels are usually of smaller transverse dimensions than those found on railways, though this is not invariably the case; but many are of great length. That at Blisworth, on the Grand Junction Canal, is 3080 yards, or a mile and three quarters long; that on the Thames and Medway Canal, which has been recently converted into a railway tunnel, is about two miles and one-eighth; one on the Leominster Canal at Pensax is 3850 yards, or nearly two miles and a quarter; and the Marsden tunnel, on the Huddersfield Canal, is 5451 yards, or upwards of three miles long. The tunnels or excavations on the Duke of Bridgewater's Canal, which is conducted by several channels into the heart of a coal mine, are said to be altogether eighteen miles long. Telford introduced, for situations where a canal is greatly elevated above the surface, aqueducts formed of cast-iron plates screwed together by means of flanches, and supported upon piers or pillars of masonry. The first aqueduct of this kind was that for carrying the Shrewsbury Canal across the Fern valley at Long Mill; but the most extensive and remarkable is the Pont-y-Cysylte, which carries the Ellesmere and Chester Canal over the Dee at an elevation of about 125 feet above the bed of the river. The trough or aqueduct is 988 feet long, 20 feet wide, and 6 feet deep, and it is supported by 19 pairs of stone pillars, 52 feet apart.

Unavoidable changes of level are usually overcome by *locks*, the invention of which has been disputed by the Dutch and the Venetians. Leonardo da Vinci is said to have applied them in 1497 to the Milanese canals. A lock is a chamber of masonry constituting the bed of the canal between the upper and lower levels, at the point where it is desired to transfer boats from one to the other, and is furnished with gates at each end, and with sluices communicating with both the levels. When a boat is to be passed from the lower to the upper level, the water is suffered to escape from the lock until its surface coincides with the lower level. The gates at the lower end are then opened, and the boat is floated into the lock. The sluices which communicate with the upper level being then opened, the level of the water in the lock is raised until it coincides with the upper level of the canal. The upper gates are then opened, and the boat is floated out of the lock. The operation of lowering a boat is precisely the reverse. Every time the operation is performed, a quantity of water, equal to the contents of the lock, is lost from the upper level. To make this loss as small as possible, locks are made only just wide enough to admit the widest boats used on the canal; and in some cases two are formed side by side, with a communication between them, so that, whenever one has to be emptied, one-half of its contents may be transferred to the adjoining one, and saved for a future occasion. This arrangement also saves time. Inclined planes, up and down which the boats may be conveyed on trucks or sledges, have in a few cases been used as substitutes for locks.

The usual mode of moving boats upon a canal is to *tow* or draw them by means of a long rope, by horses driven along a raised *towing-path* formed along one bank of the canal. To save expense, the older canal bridges were made so small that it was necessary to detach the horses on coming to them, and to get the boats through by manual labour, or by mere impetus; but on the best modern canals the arches are made large enough to include a towing-path as well as a water-way. The same remark applies to tunnels. In several of the older tunnels the boats were forced through by the laborious and dangerous process of *legging*, which was performed by men lying upon their backs on the boat, and thrusting their feet against the sides or roof of the tunnel. In some cases, ropes or chains worked by steam - engines have been used for hauling boats through. The attempts made to propel canal-boats by steam-power, have been of questionable success. Paddle-wheels of every kind disturb the water so much as to injure the banks. In 1844 screw propellers were for the first time used on canals in Scotland, on the Union Canal. The steamer was a tug-boat, capable of drawing eight or ten heavily laden barges: it had two Archimedean screws on either side of the bow. A steam tug was tried on the Grand Junction Canal in 1845, provided with a submerged propeller invented by Captain W. H. Taylor, differing somewhat from the screw-propeller. It produced scarcely any wave when going four miles through the water, and gave promise of being a useful means of traction for goods traffic. On the Glasgow, Paisley, and Androssan Canal fly-boats for passengers, drawn by horses at a considerable speed, have been run successfully: but, amidst conflicting statements, it is difficult to decide whether in any case the ordinary walking pace of a horse can be exceeded on a canal without a greater loss of power than would attend the like increase of speed upon a railway or perfect road. From experiments made while railways were yet in their infancy, it would appear that, while at a very slow pace heavy goods may be conveyed much more economically on a canal than in any other way, the economy turns in favour of a railway where the velocity exceeds four miles per hour, while at high velocities the economy of the canal disappears even as compared with an ordinary road.

Mr. Watson patented in 1839 a form of canal boat which could be lengthened or shortened according to the length of the lock which it had to pass through. It was divided into two or more separate and independent water-tight portions, connected together by means of hinges or coupling links and bolts; so that they might either be separated and placed side by side, or the ends turned round and doubled back without being unhinged or uncoupled.

A singular mode of ascending and descending canals was proposed by the late Mr. Smith of Deanston, as a means of saving expense in locks and gates at changes of level. He proposed to divide the canal into a series of basins, the water levels of which should be from 12 to 18 inches above each other. The extremity of each basin is so contracted as to permit only the free passage of a boat; and at this spot is placed a single gate, hinged to a sill across the bottom; the head pointing at a given angle across the stream, and the lateral faces pressing against rabbits in the masonry. The gate is constructed of buoyant materials, or made hollow so as to float and be held up by the pressure of the water in the higher level. On the top of the gate is a roller to precipitate the passage of boats. When a boat is required to pass from a higher to a lower level, the bow end, which must be armed with an inclined projection, depresses the gate to as great a degree as the depth of the immersion of the boat, and as much water escapes as can pass between its sides and the walls of the contracted part of the basin. The same action takes place in ascending, except that a certain additional amount of power must be expended to enable the boat to surmount the difference of level between the basins.

The canals which have been commenced and completed in the United Kingdom, since the year 1800, are thirty in number, and extend about 600 miles. Mr. M'Culloch gives a list of British canals, with the numbers of shareholders in the proprietary of each, the amount and cost of shares, and the price on the 27th of June, 1843. The Erewash, with 231 shares, each 100*l.*, returned a dividend of 40*l.*, each share being then worth 675*l.* The Loughborough, with only seventy 100*l.* shares, the average cost of each share having been 142*l.* 17*s.*, had a dividend of 80*l.*, and a selling price per share of 1,400*l.* The Stroudwater, with two hundred shares of 150*l.*, returned a dividend of 24*l.*, with a price in the market of 490*l.* On the other hand, the 50*l.* shares of the Crinan were then selling at 2*l.* The 50*l.* shares of the North Walsham and Dillon were of the same almost nominal value in the market; and the shares of the Thames and Medway, with an average cost of 34*l.* 4*s.* 3*d.* were worth but 1*l.* Of the cost expended in the construction of the canals of England, there is no means of giving a precise account, but the following calculation seems sufficiently accurate. In round numbers, the 250,000 shares of the forty principal canals averaged an expenditure of 100*l.* per share, the result would be 25,000,000*l.*, and perhaps we may estimate the canals of the United Kingdom to have cost 35,000,000*l.*, or one-tenth as much as the railways already sanctioned.

In 1846 a canal was opened, under the name of Ludwig's Kanal, from Bamberg to Khleim, in Bavaria. It unites the Rhine with the Danube; so that a vessel could cross Europe from Rotterdam to the Black Sea; and in so far it carries out an idea which had been suggested in early times by Charlemagne.

One of the most interesting features at the present time, in respect to canals, is the project for a ship-canal over the isthmus which connects North and South America. A convention was signed at Washington in April 1850, between the British and United States governments; by which both governments promise their protection, though no pecuniary support, to a company formed for cutting the Nicaragua ship-canal.

There has also recently been a revival of the very ancient plan for cutting a ship-canal through the isthmus of Suez, to connect the Mediterranean with the Red Sea.

CANARIES. These islands are fruitful in produce. On an average of the last few years they have produced wheat, maize, barley, millet, and rye, 170,000 quarters; wine, 54,000 pipes; barilla, 300,000 quintals; and potatoes, 500,000 barrels. The chief foreign trade is with England, the United States, and Hamburg: there is also an active trade between the islands. The number of foreign vessels which visit the islands annually is about 120. The principal ports are Santa-Cruz and Orotava in Teneriffe, and Palmas in Gran-Canaria. The exports consist of wine, fruits, corn, barilla, honey, orchilla, moss, fish, cochineal, raw silk, &c.; the imports are woollen and cotton cloths, linen, silks, colonial produce, brandy, paper, oil, glass, hardware, &c. There are important fisheries along the coast of Africa.

The exports of British and Irish manufactures to the Canaries have varied, during the last twenty years, from 20,000*l.* to 60,000*l.* per annum. In 1848 they were 45,832*l.*

In the chief island, Teneriffe, the quantity of wine annually made amounts to 3,000,000 gallons; the best sort, called Vidonia, which resembles Madeira, is exported to England. Coffee has been cultivated with success; iron ore is found, and sulphur abounds on the Peak of Teyde. Linen and woollen stuffs are manufactured by each family generally for its own use. Some silk stuffs, earthenware, soap, vermicelli, leather, brandy, ropes from the agave, hats, baskets, and mats of palm leaves, are the other chief articles of manufacture.

CANDELA'BRUM, was an article of furniture used by the Romans both in their public edifices and private dwellings. The candelabra used in public edifices were usually of a greater size than those for private dwellings, and were made with a large cup at the top to receive a lamp or sufficient unctuous material to feed a large flame.

In the Townley collection, in the British Museum, there are several bronze candelabra from 12 inches in height to upwards of 5 feet, and of various patterns. They are mostly flat on the top, although some are formed with a cup-like top, as if for a large flame. One has a spike to receive a clay lamp, with a hole in the centre. Two exquisite works of candelabra, carved in marble, are preserved in the Radcliffe Library, Oxford.

CANDIA. This once-celebrated island is still rich in produce, though fallen from its high position. It contains extensive woods, pastures, and meadows; and produces corn, wine, oil, opium, liquorice, flax, cotton, silk, carobs, oranges, lemons, dates, and other southern produce. Besides the common domestic animals, game, wild sheep, chamois, goats, bees, and fish are very numerous and abundant. About 600,000 sheep and goats are fed on the mountains; their wool is coarse, their milk is made into cheese. There are in the island about 50,000 horned cattle, which are used chiefly for ploughing: the milk of cows is not used, there being a prejudice against it. The habitations of the peasantry are rude in the extreme, and their clothing consists of coarse cottons, linens or woollens, manufactured by each household. The chief manufacture is soap, which is highly esteemed all through the Levant. The principal exports are oil and soap; the imports are some British and Austrian manufactured goods and metals, colonial produce and corn. Every article produced on the island pays one-seventh to the government. In lieu of a tax on silk, the mulberry trees are rated.

CANDLES AND CANDLESTICKS. Candles are commonly made of tallow; but wax, spermaceti, stearine, palm oil, and other materials are also employed. A wick, mostly formed of cotton fibres, passes through the candle. The action of this wick is merely mechanical, serving in the first instance by the heat given out during its combustion to fuse that portion of the tallow or wax to which it is more nearly applied, and then to take up through its fibres the fluid matter, which is thus prepared by minute division for decomposition and combustion. In order to ensure the proper burning of the candle, the wick requires to bear a given relation to the thickness of the candle.

There are two ways of making candles, which are distinguished as *dipped* or *mould* candles, according to the method employed. Dipped candles are made as follows:—Wicks made of spun cotton are selected of a size proper for the intended diameter of the candle, and are cut into the requisite lengths by a simple and convenient machine, being first doubled and twisted so as to leave a loop at one end. Into this loop a smooth cylindrical stick half an inch in diameter and about three feet long is inserted, and several of the cottons or wicks, being so treated and disposed at regular intervals on the stick, are ready to receive their external coating of tallow. The number of cottons ranged upon each stick varies according to the size of the candles to be made. The tallow, being previously melted and strained, is placed in a kind of trough, into which the wicks are dipped three times for the first 'lay;' after being kept a short time over the trough for the wicks to drain, the sticks are placed on a rack from which the candles hang freely, and are thus allowed to harden. The same process is repeated a second and a third time and oftener, according to the required weight of the candles. Where large quantities are to be made, several sticks are placed together in a kind of frame, and are lowered into the melted tallow and raised again by machinery, a counter-weight being used in order to indicate when the wicks have taken up the required quantity of tallow.

Mould candles are made in cylindrical moulds of pewter, one end of which is smaller than the other to allow of the easy removal of the candles.

From 10 to 16 of these moulds are placed together in a wooden frame, so that their larger ends terminate in a kind of trough common to the whole; the wicks are inserted and kept firmly in their proper places in the centre of each cylinder by strong wires. The frame being then placed with the trough uppermost, the moulds are filled with melted tallow and are placed in the air to cool, after which the wires by which the wicks are fixed are withdrawn, the superfluous tallow is removed from the trough, and the candles are pulled out of the moulds.

The process used in making wax candles is different. The wicks being cut and twisted in the manner above described, a set of them is suspended over a basin of melted wax, which is taken up by a large ladle and poured from time to time on the tops of the wicks, and the melted wax running downwards adheres to and covers the wicks throughout their length. This is repeated until a sufficient weight of wax has been gathered upon each. After the candles are sufficiently cooled, they are rolled upon a smooth table in order to give them a perfectly cylindrical form, and they are then polished.

The candle manufacture is distinguished by many interesting features. In most cases the processes are little other than of a handicraft character; but in large establishments machinery is more and more introduced. At the great soap and candle works in London, and at other establishments of magnitude elsewhere, store or dip candles are made by dipping as at other places; but a greater number are dipped at one time. Twenty to twenty-four candles, for instance, are hung on one broach or stick; thirty broaches are ranged side by side to form a frame; and thirty six frames are suspended from a machine which is capable of being brought over the vat of melted tallow. There may thus be twenty to five and twenty thousand candle wicks suspended from one machine, and all the candles made by one man and a boy in less than a day.

At several of the larger and more important establishments, a beautiful machine is now employed for making mould candles. The wick is wound on a reel in lengths of 100 feet, of which there are as many as there are moulds. In a kind of frame are enclosed a certain number of moulds, with a reel of cotton attached to each. A portion of cotton is unwound from each wheel, and made to pass through a mould, the lower end of which is only large enough to admit of the passage of the wick. The frames are then so arranged that the melted tallow can be made to flow into them; and when the tallow has solidified, the frames are laid on their side, and by a beautiful adaptation of mechanism, the candles are forced out of the moulds, and thrown on a table in parallel lines; after which the wicks are cut to a proper length.

The novelties in the manufacture of candles, and in candlesticks adapted to them, have been very numerous within the last few years. Patents have been obtained for candles made of palm oil, which is solid in our climate, though liquid in Africa. Stearine and margarine are also employed for this purpose. *Palmer's* candles are distinguished chiefly by the use of a wick which, bending out to the hottest part of the flame as it burns, consumes without the necessity of snuffing. But the chief feature in Palmer's patents is the use of a candlestick which maintains the candle always at the same height; there is a spring beneath the candle, which presses it upwards with such force, that the top of the candle is always maintained on a level with the top of the candlestick, the wick alone protruding. The construction of candles with wicks so contrived as to require no snuffing, has often engaged the ingenuity of practical men; but in most cases the attempts have failed. A kind of candle lamp was introduced a few years ago, in which solid tallow is placed within a lamp, and melted as it is required for burning.

One of the patents obtained by Mr. Palmer in 1849, relates to several improvements in the manufacture of wicks for candles. The first is the formation of helical or spiral wicks, consisting of a number of strands bound together by cross gymp; with one strand stiffer than the rest, to retain the wick in its proper position. The second form consists of cotton cord, twisted hard and firm. The third is the formation of wicks plaited on a wire, which wire is afterwards withdrawn to leave a space for capillary action of the melted tallow. The fourth is for coating one of the strands of a wick in a metallic envelope, by dipping it in melted bismuth.

Mr. Maudslay patented a remarkable machine in 1847, for making candles by a sort of tube-drawing process, something akin to the Italian mode of making maccaroni. The tallow or composition is brought to a soft warm paste-like state, and in that state is forced through a tube kept cold by immersion in water; it gradually solidifies during its passage through the tube (which is of considerable length, and is coiled round a circular vessel), and is discharged into water, where it at once assumes a solid form. At one particular point before the tallow has solidified, an end of cotton wick is introduced into the tube, and is drawn in and enveloped by the tallow as it passes. The theory of the machine is such that it could produce an *endless* candle, which may be cut by simple machinery to any given length. The machine is remarkably novel and ingenious in its arrangements.

The Patent Candle Company's works at Vauxhall and Battersea are interesting, as showing the application of chemistry and of mechanism on a large scale to this manufacture. Besides the steam-engines and hydraulic presses, 700 men are employed, and 4,000 tons of palm and cocoa-nut oil are used per annum. The cocoa-nut oil is chiefly procured from Ceylon, but the palm-oil (which is the chief ingredient in the patent candles) from Africa. The palm-oil reaches this country in a semi-solid state. It is first liquified by passing a steam-pipe through it, then converted by chemical processes into a colourless concrete mass; then cut by a rotatory machine into slices, which are placed one upon another, with cocoa-fibre mats between them, and iron plates between the mats. These bundles are taken to a room where are forty-two powerful hydraulic presses, worked by steam power; and this immense pressure is applied, first cold and then hot, to force out the oleic acid from the palm-oil, leaving the solid stearine behind. This stearine, after being again liquefied, is in a fit state for use in making candles, which is effected by the patent moulding machine. The company spin their own wicks (29 miles of which form the preliminary "cottoning" of one machine), and conduct several other subsidiary arrangements on a large scale, involving the combustion of 160 tons of coals per week.

There are many curious little pieces of mechanism, patented within the last few years, having for their principal object the mode of adjusting candles in candlesticks. One consists of a candle shade constructed in a circular ring, which ring is suspended from a conical cap resting on the top of the candle; as the candle burns this cap sinks with it, and by that means, the shade maintains a constant level relatively to the flame of the candle. Another little piece of apparatus consists of a wire-frame for supporting a shade, and which is itself supported by having a sort of circular spring hoop, which clasps the candle. Many varieties of wedges and springs have been devised for fixing candles into the candlesticks. An ingenious self-acting extinguisher for candles was invented a few years ago, but we believe not patented. A steel spring clasps the candle firmly within its jaws: and the extinguisher is hinged to the handle of this spring by a bent arm. A wire projects from the arm of the extinguisher, and thrusts into the solid part of the tallow of the candle. When the candle has burned down so as to soften the tallow around the wire, the latter slips aside by being no longer able to maintain its position; and the extinguisher falls over the flame of the candle. By adjusting the wire to any particular distance below the wick, the candle can be extinguished after any given amount of time.

Among the almost endless variety of new candlesticks is one patented in 1849 by Mr. Sturges of Birmingham. Where the general character and pattern of a candlestick are such as ill fit it to be finished in a lathe, Mr. Sturges proposed to cast it with melted metal in moulds, which moulds are kept slowly rotating during the casting.

The export of candles for the first nine months of 1850 amounted to 2,033,280 lbs.

CANE. [Calamus.]

CA'NNABIS. [Hemp.]

CANNON. The invention of cannon is noticed under Artillery, and matters relating to their use under Gunnery. Cannon are not cast hollow, it being found that if so cast they would not, owing to the irregular cooling of the metal, be equally strong in every part. Being cast solid, the outside cools first, with a close sound grain, and all the porous or spongy parts of the metal are found in the centre. This is subsequently turned or bored out in an engine-lathe, which leaves the inner surface perfectly true, and the bore of the requisite diameter.

Mr. Maudslay has recently proposed to the government the use of cannon having a peculiar form of breech. Under ordinary circumstances, cannon are loaded, and sponged after firing, at the mouth; but it has long been felt that if these operations could be performed at or near the remote end of the cannon, the change would be accompanied by greater rapidity of firing, less exposure to the enemy, and a diminution in the number of hands employed. According to Mr. Maudslay's plan, the cannon is bored quite through; but a moveable breech is provided, which is fixed after the cannon is loaded, but is removed for the sponging and re-loading. A lever, rack, and pinion are provided for fixing and unfixing the moveable breech.

CANOPUS is the name of an Egyptian jar of a big-bellied form, with a cover or top representing a human head or that of some animal. These vessels are generally made of baked earth, sometimes of alabaster, and even of green basalt. Some have hieroglyphics on them, and are painted and glazed. Bodies of sacred animals are sometimes found in these vessels. Earthen jars of this form seem to have been used for keeping water cool, as they still are in Egypt.

CANOPY, the covering over a niche used in Gothic architecture. They are usually elaborately carved, being intended not merely as a covering, but also as a mark of distinction. The various Gothic edifices in England present numerous examples of canopies; of which Henry the Seventh's chapel at Westminster Abbey is perhaps one of the most striking.

CANTAL, one of the southern departments of France, is rich in pastures. The number of horned cattle reared for exportation and for the purpose of making butter and cheese is immense. As much as 50,000 quintals of cheese is annually made. In mineral wealth the department is also rich; copper, iron, lead, sulphur, alum, antimony, coal, limestone, slate, granite, &c., are found, but the only mine worked is one of coal. The manufacturing industry of the department is of little importance; it is confined to the making of lace, copper vessels, coarse stuffs, glue, and leather. At the end of autumn many of the population emigrate to Paris and other parts of France, where they find employment as porters, water-carriers, tinkers, and handicraftsmen, returning home in the spring of the following year, or in some instances after an interval of several years, for the inhabitants are strongly att ched to their poor, wild, but highly picturesque country.

CANTEEN, a small wooden vessel capable of containing three pints, which is carried by each soldier on the march on foreign service or in the field. The use of them has been for some time general in the British army. Another kind of canteen is a square box fitted up with compartments, in which officers on foreign service pack a variety of articles.

CA'NTHARIS, or *Spanish Fly*, is largely imported for medical use, on account of a pungent volatile principle contained in the insect. The insects are killed in vinegar, dried on hurdles, and packed for use. Though bearing the name of Spanish Blistering Flies, the greatest quantity is obtained from St. Petersburg; and the Russian insects are superior to those from Sicily or France. When good, they are of a shining yellowish green colour; the odour is strong and disagreeable; and the taste acrid and caustic.

The active principle of these insects is a white substance, which may be obtained in the form of small crystalline plates. To this principle the name of *cantharidin* has been given. Cantharidin may be extracted in various ways. It is so powerful, that one-hundredth part of a grain applied to the skin will excite vesication.

CANTILEVER, or bracket, a projecting piece of wood, stone, or iron, which supports a cornice, balcony, &c.

CANTON. The trading and manufacturing features of this city are highly interesting.

The shops are commonly quite open towards the street, that is, those appropriated to Chinese customers; for the few streets devoted to European trade are rather on a different plan, the shops being of a closer structure, and less exposed to external observation. The several streets are commonly devoted to distinct trades. By the side of each shop is suspended from on high a huge ornamental tablet of wood, varnished and gilded, on which are described the particular calling of the tenant and the goods in which he deals. Some of the shops, which are pretty richly supplied, are much exposed towards the street; but the inhabitants of each division generally combine into a system of watch and ward for common protection, and during the night the streets are closed at each end by doors, which are guarded by the regular police.

No inconsiderable part of the population lives upon the river, in the junks, barges, and small boats. The space opposite to Canton and its suburbs resembles a floating city. By far the largest part consists of boats which are generally not more than 10 or 12 feet long, about 6 broad, and so low that a person can scarcely stand up in them. Their covering consists of a bamboo or mat tilt, shaped like that of a waggon, which is very light, and serves tolerably as a defence against the weather. Whole families live in these boats, and are considered as a distinct part of the population, being under a separate regulation, and not allowed to intermarry with those on shore.

The whole frontage of the buildings in which foreigners of all nations are shut up together for the prosecution of their trading business at Canton does not exceed between seven and eight hundred feet. Each front, of which there are about thirteen, extends backwards a hundred and thirty yards into a long narrow lane, on each side of which, as well as over arches that cross it, are the confined abodes of the English, French, Dutch, Americans, Parsees, and others.

The European factories are called by the Chinese *Hongs*, this word hong being always used by them to denote a commercial establishment or warehouse. Near the factories are the warehouses of the several Hong merchants, all of them communicating with the river by wooden stairs, from which the tea and other goods are shipped. The shops, instead of being set out with the showy and sometimes expensive front of an English or French shop, are closed in by gloomy black shutters, and very ill lit by a small sky-light, or rather a hole in the roof.

Canton is one of the five ports of China, at which, according to the treaty with the Chinese of August 29, 1842, British subjects are permitted to trade. The principal stipulations in that treaty have since been very fully carried into effect, under a series of general regulations, subject to occasional interruptions.

By far the largest article of export from Canton is tea. The other chief exports consist of silver, silks, and china-ware. Exports have frequently exceeded 4,000,000*l.* annually. The imports consist of woollen goods, cotton, cotton-yarn, long cloths, and various other articles of British manufacture.

Canton has few native manufactures or products suitable for deposit in the Great Exhibition of 1851; but its merchants have contributed towards the subscribed funds.

CANVAS. As exemplifications of hempen canvas, we cannot do better than refer to those important uses of it described under FLOOR-CLOTH MANUFACTURE; and SAIL-MAKING.

CAOUTCHOUC. This remarkable substance is produced by the *Siphonia elastica*, the *Ficus elastica*, the *Urceola elastica*, and many other American and Asiatic plants. It is often termed *India rubber*, from its use in removing pencil traces from paper. It was in the year 1735 that this substance was first discovered by De La Condamine to be the inspissated juice of a tree. In a pure state, it is insipid and scentless, white, extremely elastic, inflammable, not altered by exposure to the air, insoluble in water and in alcohol, soluble in æther and in the essential oils, acted upon by alkalies, and decomposed by concentrated sulphuric and nitric acids.

In order to obtain caoutchouc, the trees which produce it are pierced in the rainy season, upon which a thick juice of a yellowish white colour exudes, which becomes darker by exposure to the air. If this juice be kept in well-corked bottles, it may be preserved for some time without undergoing much change, and it has been imported in this state; but, however perfectly the atmosphere may be excluded, it will ultimately solidify. Heat coagulates the juice and separates the caoutchouc: alcohol and acids produce the same effect. If exposed to the air in thin films, it soon dries, losing from one-third to one-half of its weight: and leaving caoutchouc of the usual appearance. By the natives of South America it is applied in successive coats to the surface of clay models of bottles and of animals, and dried over fires, the smoke of which communicates to it a dark colour. While the caoutchouc is still soft, various lines are drawn upon it with a blunt tool, which remain permanently impressed. When the whole has become dry, the clay is crushed and shaken out of the bottles.

The import of caoutchouc in 1849 amounted to 5328 cwts., and in the first nine months of 1850 to 4899 cwts.

The varied useful purposes to which this singular substance is applied are noticed under INDIA RUBBER MANUFACTURES.

CAPE OF GOOD HOPE. This colony will probably play an important part in the future industrial history of nations. The immigrants have yet been too few to place the colony in a high position; but Cape Town, Graham Town, Port Elizabeth, &c., are rapidly growing in commercial importance, and the inner country is year by year producing more and more of the raw materials of manufacture.

The exports of British and Irish produce and manufactures to the Cape of Good Hope at several periods five years apart, were as follow:—

1830	..	£330.036
1835	..	326,921
1840	..	417,091
1845	..	648,749

In 1848 they amounted to 645,718*l.*; but in 1849 they lessened to 520,896*l.*

During the first seven months of 1850, 296 vessels arrived at the Cape with cargoes; against 275 in the same period of 1845. Port Elizabeth (Algoa Bay) exported produce to the value of 80,000*l.* during three months only of 1850; the exports included 1,167,273 lbs. of wool, and 228,335 lbs. of gum. Graham's Town is also rapidly rising as a place of export.

A sub-committee is arranging the details of a transmission of South African produce, to the Great Exhibition of 1851.

CAPE VERDE. The Cape Verde Islands are rich in plants. Maize and rice, the chief food of the people, oranges, melons, pomegranates, bananas, lemons, figs, guavas, are the chief products. The fruits are of the best quality. Sweet potatoes are grown; the sugar-cane and the vine are cultivated, but it is prohibited to make wine. The palm, tamarind, and adansonia are the principal trees. Turtles are abundant in the neighbouring seas. Salt is made from sea water by solar evaporation, and is an important article of export to America and the coast of Africa. Orchilla is gathered for the government. Besides salt and the products above named, the principal exports are goat skins and asses to the West Indies.

The exports from this country to the Cape Verde Islands are but small: seldom above 2000*l.* per annum; in 1848 they were however 3,324*l.*

CAPERS, are the flower-buds of a plant which grows naturally upon rocks and ruins all over the south of France and Italy, rendering them inconceivably gay with its large white blossoms, from the centre of each of which there springs a long tassel of deep lilac stamens. The quality depends exclusively upon the age at which they are gathered, the smallest and youngest being the dearest and most delicate, and the largest and oldest the coarsest and cheapest. On an average each plant of the Caper-bush gives a pound of buds. The consumption of capers in this country is inconsiderable.

CAPILLARY ATTRACTION and REPULSION. If a tube of very small diameter be plunged into a fluid, the fluid in the tube either rises above or sinks below the level of that on the exterior, and at the same time is slightly curved at its upper surface. In cases where the fluid stands higher within the tube than without, as is the case with water and glass, its upper surface is always concave; but when the fluid is lower within the tube, as with mercury and glass, it is convex. These phenomena are the results of what are termed *capillary attraction* and *repulsion.*

The laws according to which a fluid thus rises or falls are as follow:—1. When a tube of dry glass is plunged in a vessel of water, the attraction of the glass does not extend beyond the depth of the very thin film of water which would adhere to the interior surface if the tube were drawn out. 2. If the tube previously moistened by such film were plunged in water, the rise would be much less than in the other case; and, whatever be the substance of the tube so moistened, the elevation of the water in it is found to be the same. 3. When cylindrical tubes of different diameters are compared, the elevation is inversely proportional to the diameter. 4. If the interior of the tube be conical, the elevation or depression in it is found to depend on the diameter at the upper part only of the elevation; and to be the same as in a cylindrical tube of that diameter. 5. If the tube be double (one tube within another), the fluid rises to the same height in the interval between the two tubes, as it would do in a tube with that interval for its radius. 6. Between two parallel plates immersed at a very small interval, the fluid rises as high as in a tube with that interval for its radius. 7. Between two plates vertically placed, but inclined at a very small angle (like a double screen nearly closed), the fluid rises higher and higher as we proceed towards the upright line of junction; and the curve of the upper surface of the fluid is an hyperbola.

As an example of capillary action exemplifying itself in every-day processes, we may mention the wick of a candle or lamp, in which oil or melted tallow rises solely by virtue of this power.

CAPITAL is a term used in commerce to express the stock of the merchant, manufacturer, or trader, used in carrying on his business, in the purchase or manufacture of commodities, and in the payment of the wages of labour; and is understood not only of money, but of buildings, machinery, and all other material objects which facilitate his operations in trade. The term itself and the practical qualities and uses of capital are sufficiently understood in this its commercial sense. But capital, in a more extended form, embraces not only the capital of particular individuals, but the entire capital of a country. In this latter sense capital may be defined as the products of industry possessed by the community, and still available for use only, or for further production.

Capital is first called into existence by the natural foresight of man, who even in a savage state discerns the advantage of not immediately consuming the whole produce of his exertions in present gratification, and stores up a part for his future subsistence. The greater proportion of mankind possess this quality, and those who do not are admonished of its value by privation. A desire to accumulate some portion of the produce of industry being natural to mankind and nearly universal, the growth of capital may be expected wherever the means of accumulation exist; or, in other words, wherever men are not obliged to consume the whole products of their labour in their own subsistence. From the moment at which a man produces more than he consumes he is creating a capital; and the accumulated surplus of production over the consumption of the whole community is the capital of a country.

The relation of capital to manufacturing industry forms one of the most important departments of study in political economy.

CAPRIFICATION is the process by which the maturation of the fig is accelerated in the Levant. It is well known that fruits which have been bitten by insects ripen sooner than others, the wound appearing to act as a stimulant to the local action of the parenchyma. This is turned to account by the Greeks in the following manner, which is called Caprification. When the cultivated fig is preparing for becoming ripe, a quantity of the branches of wild fig trees are brought into the fig orchards and placed upon the cultivated plants. The wild figs bring with them a great number of a small insect called *Cynips Psenes*, or *Dipôllepis Ficûs Caricæ*, which fly among the cultivated figs and pierce their fruit for the purpose of laying eggs. This not only brings about an earlier ripening of the fig crop than would otherwise be obtained, but enables the cultivator to obtain two harvests a year. It is however said that the practice deteriorates the quality of the fruit. Caprification has been artificially imitated by puncturing a fig with an awl, and introducing a little oil into the wound, for the purpose of preventing its healing too soon.

CAPS, PERCUSSION. It is explained in ARMS how the earlier kind of fire-arms were discharged. The percussion-cap is a modern contrivance for this purpose. It depends on the property possessed by several chemical substances of exploding by a blow or percussion. Fulminating mercury was the first substance employed in this way; but as soon as it became known that a slight blow would explode certain powders, and that this explosion would ignite gunpowder, numerous improvements were introduced by degrees. Various salts and other chemical compounds, such as some of the chlorates, nitrates, and fulminates, will explode in this way, the most familiar example of which is afforded by the 'lucifers' or 'congreves' now sold so cheaply in the streets, and which ignite so readily by friction (in effect a series of minute percussions).

When the method was first introduced, there was some difficulty in causing the explosion of the mixture to ignite the gunpowder. But this is now effected by putting the detonating mixture into a little copper box or cell called a *cap*, which is adjusted over the touch-hole, and so arranged that a smart blow bursts the cap and explodes its contents: the little cell itself is destroyed, so that a new one is required for each firing. The size of the cell, or 'percussion-cap,' the nature of the mixture, the quantity employed with each charge, and the mechanism for firing it, have been the subjects of many improvements within the last few years, some of which are patented. The caps are now made in large numbers at Birmingham, in much the same manner as metal buttons, blanks being cut out of sheet copper or mixed metal, and stamped or pressed into the proper shape. One of the recent inventions has been to make the cap double, or one cap within another, with the mixture between the two, and a small hole in the inner one to communicate with the gunpowder.

Many contrivances have also been suggested for applying these caps under a modified form to larger guns; and the detonating compounds themselves have been brought into use for exploding the contents of bombs and shells.

CA'PSICUM, or Bird-Pepper. The shell

of the fruit of this plant is fleshy and coloured, and contains a pungent principle, which also exists in its seed in great activity. On this account both the fruit and seeds of different species of capsicum are in request as a condiment, and either in the unprepared state or ground into *Cayenne pepper*, form a considerable part of the stimulating vegetables used by man. In Europe the capsicum enters largely into the seasoning of food and the preparation of pickles; and in warmer countries it constitutes one of the first necessaries of life, either green or ripe. The species from which the fresh capsicums used in Europe are principally obtained is the *Capsicum annuum*, a weedy plant found wild in South America and the West Indies. A much hotter species is the *Capsicum frutìcosum* or Goat-Pepper, a native of the East Indies, which differs from the *Capsicum annuum* in being a shrub, and in its fruit being very small.

The capsicum is easily brought to perfection in this country. Its seeds are sown in a hot-bed in the beginning of April; the young plants are managed like other tender annuals; and about the end of May they are planted in the open air under a south wall. They will readily ripen their fruit in such a situation.

CAPSTAN. [WINDLASS.]

CARAT, KARAT. The karatium was originally the twenty-fourth part of the *marc*, or half pound among the French, from whom the word came: so that three carats made an ounce. The carat was a small weight used for gold and jewels, and varied greatly in different countries. At last however it went out of use, except only in the sense in which it still exists, namely, that a carat means the twenty-fourth part of any weight of gold or gold alloy. If such a weight be all gold, it is said to be twenty-four carats fine; if one-third only be gold, it is said to be eight carats fine.

CARAVAN, a travelling body of merchants or pilgrims, who join company for safety and convenience. The term, which is of Persian origin, is confined to journeys in the East, and applies more particularly to those made in Arabia, Nubia, Syria, Persia, and Asia Minor; but the practice obtains, though mostly on a smaller scale, in many other countries where the roads are insecure, and where deserts and desolate tracts of land are to be crossed.

In the East the caravans have a commercial or a religious character, and very frequently both; the greatest of them all, or those which proceed annually to the holy city of Mecca, have always trade as well as prayers in view.

Besides these large annual caravans, others on a smaller scale are constantly occurring in the East, where merchants and travellers going the same road wait for one another until they can form a caravan, when they generally appoint one of their voluntary association to regulate the order of march. But the caravan trade is not limited to Southern Asia. The great trade between China and Russia is a caravan trade. The road runs from Peking to Kiachta, the great border-market for the barter of Chinese and European articles: the journey is from 70 to 90 days. Other similar lines of route exist in Russia and the countries to the east of the Caspian Sea.

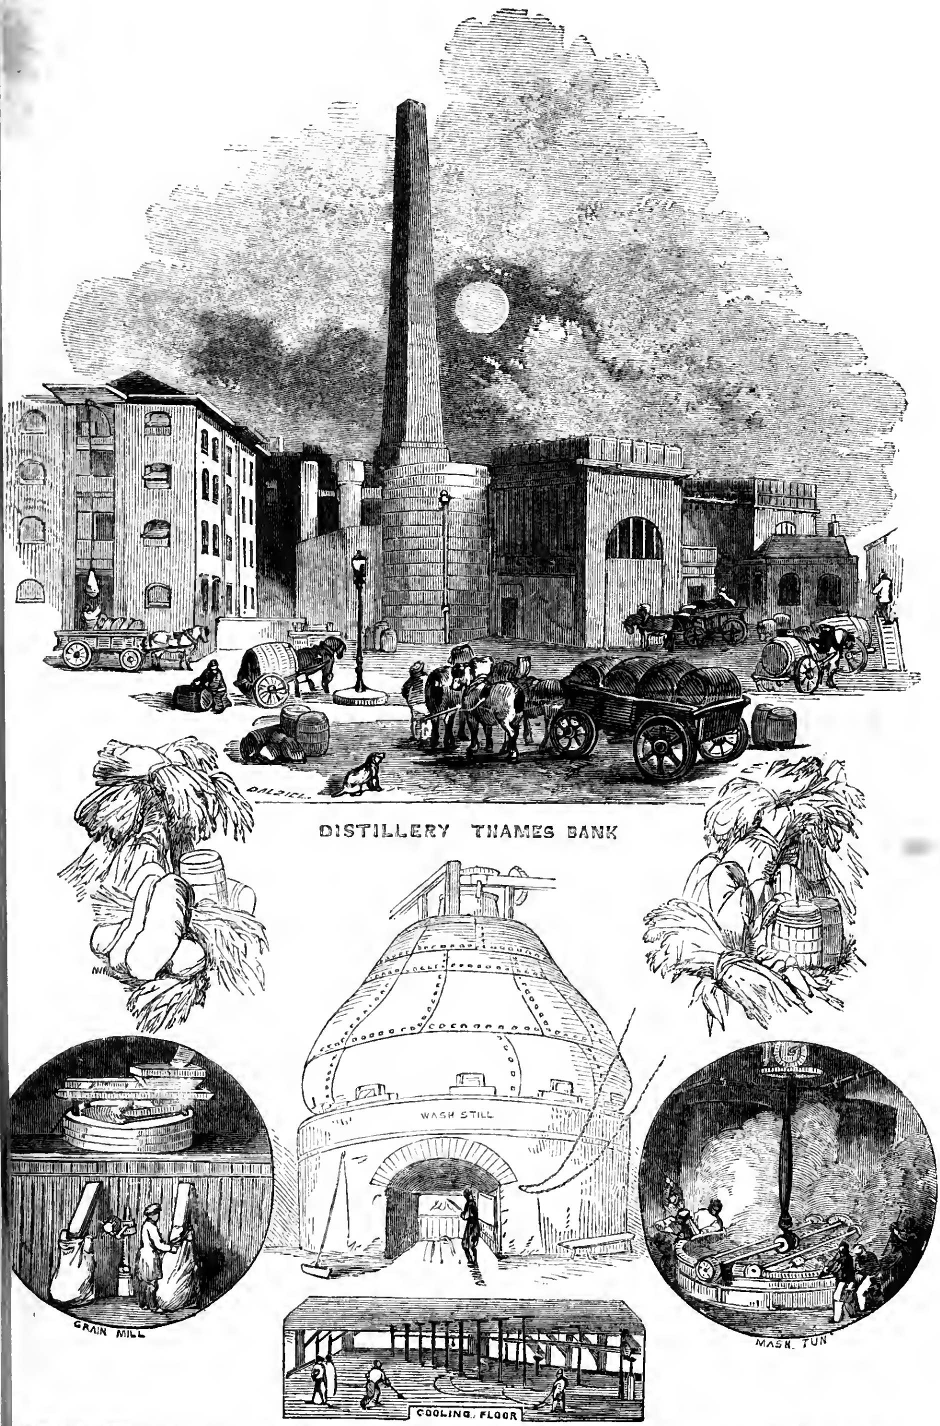
CARAWAYS, the ripe fruit of a plant called *Carum Carui*. The seeds, as they are vulgarly called, which are the furrowed halves of the ripe fruit, have a peculiar aromatic flavour, and are used as an agreeable carminative by confectioners: the roots themselves are eaten in the north of Europe.

Caraways are used in medicine as a carminative. The chief English cultivation of the plant is in Essex and Suffolk, upon old grass land broken up for the purpose. As it is a biennial, it is generally sown with another plant of the same tribe called coriander; and sometimes a crop of teazles (*Carduus Fullónum*) is raised on the same land. The three give a very valuable return during two or three years.

It would hardly be supposed, considering the minor uses to which they are applied, that caraways would be imported to so large an extent as the Board of Trade tables indicate In 1848 the importation amounted to 7,266 cwts.

CARBON, a non-metallic elementary solid body, which is widely diffused throughout nature. The purest and at the same time the rarest form in which it occurs is that of the *diamond;* the more common states in which it is met with are those of anthracite, graphite, and coal; but in these cases it is not free from admixture. Another well-known form of carbon, but still impure, is *charcoal.* Carbon is the chief element in three groups of substances:—the mineral forms, such as diamond, anthracite, &c.; the carbonates; and the vegetable series, as coal, asphaltum, peat, amber, &c.

Charcoal consists mainly of carbon procured from the decomposition of wood by burning. This operation is generally conducted in pits made in the gronnd; sometimes however it is carried on in iron cylinders. Wood is essentially composed of carbon, oxygen, and hydrogen. By the action of the heat it is decomposed the oxygen and hydrogen are ex-



KNIGHT'S CYCLOPÆDIA OF THE INDUSTRY OF ALL NATIONS.

pelled, and uniting in certain proportions form water; and also with carbon various gaseous and other compounds are formed. Among the latter are *acetic acid*, sometimes called *pyroligneous acid*, and a peculiar inflammable fluid known by the name of *pyroxilic spirit*, and *tar*.

Charcoal has the following properties. It is black, lighter than water, and full of pores, occasioned by the expulsion of the bodies volatilised. Charcoal, from whatever source procured, is absolutely infusible by any degree of heat however great; neither that of a mirror, the oxhydrogen blow pipe, nor the voltaic discharge, being sufficient to produce fusion. In its common state it is one of the worst conductors of heat known, but its power is increased after being strongly heated. Charcoal is a conductor of electricity, which is so far from being the case with the diamond, that it may be rendered electrical by friction.

Charcoal is tasteless, inodorous, and insoluble in water. It possesses the property of destroying colouring matter, especially the charcoal procured by burning bones, which is usually called *animal charcoal*. It is largely used for this purpose in sugar refining. It has the power of condensing gaseous bodies to a greater degree than most or perhaps any other substances. Charcoal is highly combustible; it burns in the air when strongly heated, though not very rapidly. During this combustion carbonic acid is formed by the union of the oxygen of the air with carbon.

It has been mentioned that charcoal is not pure carbon; when a quantity is burnt there always remains a portion of ashes containing a considerable quantity of carbonate of potash and some other alkaline and earthy salts, which have been taken up from the soil in which the tree grew that furnished the charcoal.

Charcoal is used not merely for combustion, but also for the important purpose of making gunpowder. It is also applied to other various well-known uses. Its power of absorbing gases and moisture renders it useful in some cases, while in other cases it seems to act by some power exerted on the vital energies of the system. Charcoal, especially animal charcoal, possesses the power of destroying the colour, smell, and taste of a great variety of vegetable and animal substances, particularly of mucilages and oils, and of matters in which *extractive* abounds. Meat and game too far decomposed may be restored to a condition fit for use by the employment of finely powdered charcoal, assisted by sulphuric acid. Water also may be restored from a tainted state by filtering it through charcoal. Charcoal, both from its antiseptic and vital properties, is useful in many forms of disease.

CARBONIC ACID. There are three compounds of carbon and oxygen, *Carbonic Oxide*, *Carbonic Acid*, and *Oxalic Acid*. Carbonic acid is the most important of the three. It exists largely in nature. It is in comparatively small quantity in the gaseous state in the atmosphere; it is in solution in most spring water, and in some called mineral waters to a considerable degree; but it is in solid combination that it is found in the largest quantity, forming nearly 44 per cent. of all limestones and marbles, besides occurring in less quantity united with other earths and metallic oxides. Carbonic acid is produced by fermentation; by the process of respiration; by animal and vegetable putrefaction; and by combustion, whether of oil, wax, tallow, vegetable matter, or coal.

In its uncombined state carbonic acid is a gas, colourless and transparent, and therefore invisible; it has an acid and slightly astringent taste; it extinguishes burning bodies, and is fatal to animals. On account of its great density, it diffuses slowly in the air, and hence it is apt to remain long in fermenting vats, old wells, &c., and has frequently produced fatal effects upon persons descending into them. Atmospheric air may however contain 1-20th of its volume of this gas, and be respired without becoming hurtful. On account of its great weight, it may be poured from vessel to vessel, as is shown by its extinguishing a taper repeatedly. Though gaseous at common temperatures, Faraday has showed that carbonic acid can be brought to the liquid state by intense cold and pressure: it is then a limpid colourless fluid, which M. Thilorier rendered even solid, in which state it is one of the most powerful refrigerating substances known. Carbonic acid is an ingredient in many mineral waters, to which it imparts effervescing qualities.

Carbonic acid gas is apt to be formed and accumulate in mines, particularly coal-mines, where it is termed *choke-damp*, and whence have arisen fearful colliery accidents; it is also found in old draw-wells.

Carbonic acid plays so important a part in medicine, in chemical manufactures, and in every day life, that it would be impossible even to enumerate its characteristic functions.

CARBONIFEROUS SYSTEM is the geological name for the great group of strata which includes nearly all the valuable coal yet discovered. We are concerned with it here only in respect to COAL.

CARCASS, a shell, or hollow ball of iron, perforated in three places at equal distances from each other within one hemisphere of the shell, and filled with a composition which burns with violence during eight or ten minutes. When discharged from a mortar or howitzer, the flames issuing from the perforations set fire to any building on which the carcass may happen to fall.

CARDAMOMS are the aromatic capsules of different species of a genus of plants called *Amomum*. The Malabar cardamoms are the best, and are in most extensive use. The Madagascar cardamoms are strong-flavoured. The *Grains of Paradise* are the fruit of one species of cardamoms.

CARDIFF is one of the busiest and most rapidly growing towns in South Wales. The population rose from 2,000 to upwards of 10,000 between 1801 and 1841; this increase has been chiefly owing to the shipment of the coal and iron from Merthyr Tydfil and its neighbourhood. The Glamorganshire canal, finished in 1798, was for many years the channel by which this produce reached the coast; but in 1840 the Taff railway was opened as an additional means of conveyance. The river, the canal, and the railway run nearly side by side, and terminate at Cardiff. While the railway was under construction, the late Marquess of Bute, the owner of a large amount of property in this neighbourhood, conceived the project of forming a large harbour or dock between the town and the Bristol Channel on a piece of waste ground belonging to himself. The dock, called the Bute Dock, and a ship canal leading thence to the sea, were opened about the same time as the railway. They form a work of great magnitude, on which a sum of 300,000*l.* has been expended. The entrance into the floating harbour from the sea is through sea-gates 45 feet in width; the harbour or basin has an area of an acre and a half, and is fitted for the reception of large vessels. The main entrance lock is at the north end of this outer basin, and is 152 feet long by 36 feet wide. On passing this lock the ship canal is entered, which extends to Cardiff, 1,400 yards in length and 200 feet in width, comprising a great extent of fine wharfage, and varying in depth from 13 feet to 19 feet.

Since these facilities were afforded, the trade of the port has increased rapidly. The coals shipped coastwise in 1848 were 544,196 tons, and to foreign ports 115,604—being five times as large a quantity in 1848 as in 1838. The value of the exports in 1848 was 729,094*l.* Few ports in Great Britain have increased more rapidly in the extent of their export trade than Cardiff. The number and tonnage of vessels registered as belonging to the port of Cardiff on the 31st of December, 1849, were 77 vessels, of 6,287 tons. The number and tonnage of vessels that entered and cleared at the port during the year 1849 were 9,064 vessels, of 695,022 tons.

CARDIGAN carries on a respectable amount of commerce. The number and tonnage of vessels registered as belonging to the port of Cardigan on 31st December 1849 were 249 vessels, of 14,368 tons. Many of these vessels are engaged in the Irish, colonial, and coasting trade. The number and tonnage of vessels entered and cleared at the port during 1849 were 777 vessels, of 20,170 tons.

The imports are chiefly coal, culm, limestone, and deals; the exports, oats, butter, and slates. No manufacture of any importance is carried on here. Salmon fishing is productive, and the herring fishery is of some importance.

CARDIGANSHIRE has a little mineral wealth. Veins of copper ore, lead, and sulphate of zinc occur. The mines were in the 16th and 17th centuries worked extensively and profitably. They afterwards became unproductive, and were almost wholly neglected; but within the last 12 or 14 years the spirit of mining enterprise has led to the re-opening some of the old mines and to the commencing of new ones. The lead mines are said to be most successful. The lead contains silver, varying from 14 to 80 ozs. to the ton: at Llanvair mine specimens have occurred which yielded 100 ozs. to the ton. There are slate quarries in the neighbourhood of Aberystwith, but the slate is not of good quality.

Cardiganshire is chiefly an agricultural county. The manufactures are unimportant, being confined to the weaving of a small quantity of flannel and coarse woollen stuffs. Gloves are made in the neighbourhood of Aberystwith and Tregaron. Oats, butter, and slates are exported. The decks of some of the vessels engaged during the summer in the coasting trade, are taken off in autumn, and they are used as fishing-boats. The principal imports are coal from Liverpool, culm from South Wales, Pembroke limestone, and Memel and American deals.

CARDS, CARD-MAKING MACHINE, an arrangement of wires used in the manner explained in COTTON MANUFACTURE, for disentangling the fibres of cotton preparatory to spinning. These cards are now made by a very beautiful machine. The wires are inserted in rows in strips of leather; and, by various movements of the machine, the strips of leather are pierced with holes; the wire is unwound from a coil, straightened, and cut off to the proper lengths; each wire is bent to a definite form, and then driven into the hole. One steam engine can set 100 of these machines at work at once; and each machine can form and fix 400 or 500 teeth in a minute.

CARDS, PLAYING. The manufacture of playing cards involves several processes of much nicety. The preparation of the material, the cutting into quadrangular pieces, and the stamping with the coloured device, all require careful operations. The card-board is made by many successive processes of pasting and pressing. In Mr. Dickinson's patented method, damp paper is wound over certain rollers; a paste trough with circular brushes are placed near the rollers; and during the transfer of the paper from one set of rollers to another, these circular brushes coat the surfaces of two or more papers with paste. Roller-pressure completes the operation.

Several patents have been taken out for cutting the pasteboard into strips, preparatory to a further cutting into card-pieces; of these patents, one by Mr. Dickinson will illustrate the principle generally. The machine consists of a pair of rollers, each roller having a number of circular revolving cutters; the pasteboard is passed between the rollers, where the cutters act upon it in the manner of shears, and cut it into strips, which strips are afterwards cut into card pieces.

The printing and colouring of the cards have exercised much ingenuity. In the ordinary mode of manufacture, the device is partly produced by copperplate printing and partly by stencilling in water-colours. Mr. De la Rue has patented a method of using oil-colours, and of printing in a mode very similar to that of calico-printing. The pips (hearts, spades, &c.) are set up by blocks or types, and printed at a press—the black with lamp-black ground in oil, and the red with vermilion ground in oil. The 'court cards' are printed by a series of impressions in different colours, almost precisely in the same way as that described under FLOOR CLOTH MANUFACTURE. Mr. De la Rue also employs the system of lithography, in which case there must be as many stones as there are colours, each having one particular part of the device.

The same ingenious inventor has contrived a mode of introducing gold or silver among the colours of the device. In this case all the portions of surface which are to be thus adorned are printed with gold-size instead of ink; and while this gold-size is yet moist, gold or silver-powder is sprinkled over the card: it adheres to the moistened parts, and may be lightly brushed from other places; and when all is dry, the gold will bear a careful polishing.

Some playing cards have a surface of such exquisite whiteness and smoothness as to resemble ivory; this is produced by coating them with a composition of fine French white, drying-oil, and size.

CAREX is the name of a genus of plants which render a few useful purposes to man. In the hop-grounds of Great Britain the leaves of some of the species are used for tying the bines of the hops to the poles. In Italy they are used for placing between the staves of wine-casks, are woven over Florence flasks, and occasionally employed for making chair bottoms. The leaves of the *Carex sylvatica*, according to Linnæus, are combed and dressed, and used as a warm lining for gloves and shoes; and, thus protected, the Laplanders seldom suffer from being frost-bitten.

CA'RICA, a remarkable tree found in various parts of South America, having a simple trunk, from 12 to 20 feet high, and abounding in a milky juice. The fruit is called the *papaw*, and is singularly useful in many ways to the natives where it grows. The fruit is eaten ripe, and when unripe is boiled and used as a vegetable. The juice forms a cosmetic, and the leaves are employed in washing instead of soap. It is also much used in medicine. The milky juice of the fruit is spoken of as a vermifuge; but the most extraordinary property of the papaw tree is, that animals which are fed upon the fruit are found, when killed, to be peculiarly tender.

CARLISLE. Till about a century ago, no trade or manufacture of any importance appears to have been carried on within this city: but it is now gradually rising in importance. The principal business of Carlisle arises from its manufactures of cotton goods and ginghams, and its coasting trade, which is somewhat extensive. The distance of the city from Port Carlisle, at the mouth of the river Eden, on the Solway Frith, is about nine miles; a ship canal, eleven miles in length, which was completed in 1823, connects Carlisle with Bowness on the Solway Frith. By this canal vessels of 100 tons burden can ascend to the town. A steamer plies twice a week between Liverpool and Port Carlisle. One of the principal stations on the line of railway from London to the Scottish districts by the North Western and Caledonian railways is at Carlisle. The town also possesses railway communication with Newcastle-on-Tyne and South Shields on the eastern coast, and with Maryport on the western coast. The vessels registered as belonging to Carlisle on the 31st of December, 1849, were 42, of 2107 tons. The number and tonnage of vessels entered and cleared during the year 1849 were 88[illegible] vessels of 108,115 tons.

The products of Carlisle industry will be exhibited to a limited extent at the Grand Display of 1851. Cottons, furniture chintzes, woollens, checks, and mixed fabrics, will occupy a place.

CARMINE, one of the most beautiful of the red colours used by painters. It is obtained from cochineal; and its colouring matter, called *carmin*, may be extracted by the aid of ammonia. [COCHINEAL.]

Carmine has been obtained from *dahlias*, by M. Rupprecht of Vienna. It is only the deep clear purple dahlia that will yield it; but from this variety he has obtained 235 lbs. of carmine from 200 square fathoms of dahlia beds. The carmine is said to be too fleeting for silk or cotton dyeing, but to be fitted for staining confectionary, artificial flowers, fancy paper leather, and rouge powder.

CARNELIAN, or CORNELIAN. [AGATE.]

CAROLINA. North and South Carolina supply varied produce for the commercial markets. In *North* Carolina Indian corn is raised throughout the State, and in some parts cotton. In the upper country, oak, walnut, lime, and cherry-trees of large size abound. The principal minerals are gold and iron; the gold region is on both sides of the Blue Ridge; and here the gold is found in grains, in small lumps, and in veins. The exports consist of live cattle, tar, pitch, and turpentine, lumber, Indian corn, cotton, tobacco, pork, lard, tallow, &c. Most of these are sent to South Carolina and Virginia to be exported thence.

In *South* Carolina, the principal objects of agriculture in the low plains are rice and cotton, the latter being also cultivated in some districts farther inland. The sugar-cane is only grown with advantage in the most southern part of the state. The fruits of the sea-coast are oranges, lemons, pomegranates, olives, and figs. In the upper country all the grains and vegetables of England are grown, with Indian corn in addition. The forests contain fine timber trees, especially oak, beech, and hickory. No metal abounds, except iron, which is met with in several places in the upper country. A little gold is found, and some copper and lead are wrought. To facilitate internal commerce a few short canals have been cut, especially to avoid the rapids of the rivers. The exports consist of cotton, rice, tobacco, and hides, and the imports of manufactured goods, and the productions of the East and West Indies, with wines from the countries of southern Europe.

CARPENTRY is the art of framing timber generally, and especially the chief timbers in house-building. The neater wood-work of doors, window-frames, the planking of floors, skirtings, and stairs, more properly belong to JOINERY.

Carpentry requires a knowledge of the properties of timber, and of its strength when exposed to various strains. [MATERIALS, STRENGTH OF.] This will teach the peculiar fitness of each kind of timber for its own peculiar purpose. It will show, for example, that while oak greatly exceeds fir in hardness and durability, it may be inferior to it under certain circumstances; because, while the fibres of a sawn beam of fir are so straight as to run in unbroken lines from end to end, those of a sawn beam of oak are often so tortuous as to be repeatedly divided by the saw. Seasoning, by long exposure to a current of air, is necessary to prepare timber for use in carpentry; but as the best seasoning will not entirely prevent subsequent warping, shrinking, and splitting or flying, timbers should be so fitted together as to counteract as far as may be the effect of such changes. When it is required to bend timbers, they may be softened by boiling or steaming, and then brought to and secured at the desired curvature, which, when cold and dry, they will retain with very little variation.

Illustrations of a few details of carpentry will be found under FLOOR, ROOF, SCARFING, TRUSSING, &c. The most gigantic examples of timber-work in modern times, are to be found, perhaps, in the scaffolding for the Britannia tubular bridge. In respect to one continuous flooring, the Palace of Industry in Hyde Park furnishes, perhaps, the largest known example.

CARPET. The following kinds of carpets are now made in Great Britain:—Axminster, Venetian, Kidderminster or Scotch, British or damask Venetian, Brussels, and Wilton or Pile carpeting. These names do not always denote either the present or original place of manufacture. Brussels carpets were introduced into Kidderminster from Tournay in 1745: and it is doubtful whether Venetians were ever made at Venice. Wiltons (which are in fact Brussels carpets) were made on the continent before they were introduced at Wilton; and what are called Kidderminster are made in the greatest quantities in Scotland or Yorkshire.

Axminster Carpets are usually made in one piece, according to the dimensions of the room for which they are required. The warp or chain is of strong linen, placed perpendicularly between two rolls, or beams which turn round and enable the chain to be rolled from off one beam and on to the other as the weaving of the carpet proceeds. Small tufts or bunches of different coloured worsted or woollen are tied to or fastened under the warp; and when one row of these tufts has been completed, the shoot of linen is also thrown in and firmly rammed down. Another row of tufts is then arranged in such a manner as, by a change of the colours, to form a further portion of the pattern. To guide the weaver as to the position of the colours, a small paper design or drawing constantly hangs before him, from which he works. The tufts wholly conceal the linen threads. Real Turkey carpets are manufactured in a similar manner, and they are regularly imported, though not in very large quantities. Finger or Town-made and Stormont rugs are also formed with tufts put in as they are in Axminster carpets, but with a different arrangement of apparatus.

Venetian Carpets.—Here the warp or chain which is of worsted, and generally arranged in stripes of different colours, is alone visible; the shoot, which is of a dark colour and usually black, is concealed between the upper and under surface. By using shoot of different sizes these carpets are sometimes made to assume the appearance of plaids, checks, or twills.

Kidderminster or *Scotch Carpets* are formed by the intersection of two or more cloths of different colours; but as these cloths may be woven in stripes of different shades, by introducing at intervals shoots of different colours, the carpet is usually made to assume a great variety of colours. These carpets are sometimes 'three-ply,' or have three thicknesses of cloth; but for the most part they are 'two-ply.' Each cloth is perfect in itself, so that, if one cloth were carefully cut away, the other would remain perfect, and be in appearance like a very coarse baize. The process of weaving both cloths is carried on at the same time, and in each part of the carpet that cloth is brought to the surface which is required to produce that portion of the pattern. The back of the carpet will necessarily be of exactly the same pattern as the front, but the colours will be reversed. A complicated variety of the jacquard loom is employed in weaving these carpets.

British or *damask Venetian Carpets* partake both of the character of Venetian and Kidderminster, though more of the former than the latter. The warp, as in the Venetian, is the only part seen, whereas in Kidderminsters the shoot forms by far the greatest portion of what is visible.

Brussels Carpets form by far the most important and increasing portion of the carpet trade. Brussels are composed of linen and worsted, the cloth or reticulated part of the structure being entirely of linen, which is formed into a kind of very coarse sampler cloth, with two threads of linen for the shoot (one above, and the other below the worsted). The mode of bringing up to the surface the particular worsted thread which gives the pattern requires much ingenuity in the arrangement of the Brussels loom.

Wilton or *Pile Carpets* differ from Brussels only in this: that the loops of worsted are all cut through, and the carpet assumes a velvety appearance. At Glasgow a beautiful kind of velvet carpet is manufactured, in which coloured chenille is thrown in as a shoot, and afterwards cut at the surface. The manufacture of Brussels carpet was introduced into Wilton soon after its introduction into Kidderminster: the Wilton carpets being originally a better description of goods, were distinguished by the name of Cut or Wilton Carpets.

The chief export trade for carpets is to the United States of America; but they are also sent to most parts of the continents of Europe and America. By far the greatest quantity of Brussels is made in Kidderminster: what are called Kidderminster or Scotch are made in the largest quantities in different parts of Scotland and the north of England.

Mr. Wood, of Darwen, patented in 1850 an ingenious mode of making looped or piled (or what may perhaps be termed velvet) carpets. Under the ordinary circumstances of making velvet [VELVET] wires are inserted at intervals to assist in forming the loops; and these wires have to be inserted and removed by hand. In Mr. Wood's plan of carpet making, however, wires are thrown in among the warp-threads, and removed when the weft is formed, by ingenious mechanism attached to the loom.

There is a mode of imparting colour to carpets, patented by Mr. Henshall, a carpet manufacturer of Huddersfield, in which something like the principle of calico-printing is applied to carpet-work. The object is to produce differently coloured spots, squares, or stripes, independent of the mere weaving process. The warp threads are arranged side by side in a peculiar frame, so as to form an even horizontal layer; and in that state they are drawn tightly over a printing table, and printed in colours by blocks in the usual way. When these warp threads (or they may just as conveniently be weft-threads) are applied to weaving, a pattern is produced by the variation of the colour in each thread, in addition to the primary pattern which results from the weaving process.

In a communication to the *Times* in 1845, a correspondent suggests the manufacture of cheap carpets from coarse cotton. 'There are many kinds of carpets made of cotton in India—stout, serviceable, handsome things; generally they are termed *serrigee*. These are of all sizes, from the small one, seven feet by three, which every man possesses; to enormous ones for rooms and halls. These are generally striped, red and blue, or three shades of blue, sometimes woven into patterns; and I have often thought how useful they would be in England, these coarse kinds, for the poorer classes, for bed-rooms, &c. Again, what beautiful designs might not be manufactured by the skill of English workmen,—how large a quantity of small ones for individuals, or large for halls, might not be made for exportation to Africa, South America, and even India! At Warungole, in the Nizam's country, beautiful carpets of the same description as Turkey—that is, with a nap raised—are made of cotton.

A patent has been taken out within the last few years, for a mode of manufacturing carpets by a felting process.

A carpet of a very remarkable kind is now being prepared for the Great Exhibition, by a committee of ladies of Westminster. It will be thirty feet long by twenty wide, and will consist of 150 pieces two feet square. For each piece a design has been drawn by Mr. Papworth and Mr. Simpson, the full size; and each lady, on payment of a guinea, has one design placed at her disposal, to work up into a piece of the carpet; the work is to be executed by hand in Berlin wool, which is supplied by the committee. There are to be 340 threads in each direction, in each piece; and when completed, the whole of the pieces are to be joined edge to edge to form a carpet. The whole carpet will form — not a repetition of designs—but one comprehensive design, which it is supposed could not be imitated in the loom for less than 1000*l*.

CARPOBA'LSAMUM, a kind of volatile aromatic oil, said by Bruce to be furnished by the *Balsamodendron Gileadense*. It is produced by the nuts, which have a fleshy kernel yielding the balsam by simple expression. It should be employed while recent, otherwise it loses its odour and becomes inert.

CARRIER, in a commercial sense, is one who for hire undertakes the conveyance of goods or persons for any one who employs him. In a legal sense, it extends not only to those who convey goods by land, but also to the owners and masters of ships, mail-contractors, and even to wharfingers who undertake to convey goods for hire from their wharfs to the vessel in their own lighters, but not to mere hackney coachmen. A common carrier of goods for hire is not only bound to take goods tendered to him, if he has room in his conveyance, and he is informed of their quality and value, but he is liable for their loss, except in three cases:—1, Loss arising from the king's *public* enemies; 2, Loss arising from the act of God, such as storm, lightning, or tempest; 3, Loss arising from the owner's own fault, as by imperfect packing. A carrier can refuse to deliver up goods which have come into his possession *as a carrier*, until his reasonable charges for the carriage are paid.

CARRONADES are short iron guns, differing from other guns, and from bowitzers, only in their dimensions and in the manner of attaching them to their carriages, which is by a joint and bolt underneath the piece, instead of trunnions. They derive their name from the village of Carron, in Stirlingshire, where they were first made.

When fired at point-blank, their range is about 150 yards; and, at an elevation of three degrees, it varies from 660 to 750 yards. They are extremely serviceable on land for breaching ramparts of earth, or for enfilading the faces of works; and at sea, in engagements at close quarters.

CARROT. The principal use of carrots is as food for cattle. The orange carrot and its varieties are the most common in England; but the large white and yellow carrots are more esteemed on the continent; they are supposed to contain more saccharine matter, and to produce a greater bulk of nutriment on the same extent of ground. The best method of taking up the carrots, to store them for winter use, is by means of three-pronged forks, such as are used in digging asparagus beds. The plough is sometimes used after the coulter has been removed; but, with all the care of the ploughman, the plough and the horses will cut and bruise many of the finest carrots. Carrots may be kept all winter in dry cellars, if they are protected against the frost. The more common way is to store them in straw in long trenches. The produce of carrots on good light land is nearly double that of potatoes, and they do not impoverish the land so much. From twenty to forty pounds of carrots, with a small quantity of oats, is a sufficient allowance for a hard-working horse for twenty-four hours. Where hay is scarce, it is a most economical substitute; and where the value of urine is known carrots are much prized, as they greatly tend to its increase.

If carrots are cut in pieces and steamed, they become more nutritious, and the expressed juice made to ferment affords by distillation a very good and wholesome spirit.

Sugar may also be extracted; but the carrot is inferior to the beet in this respect.

Carrot seed to the amount of 22,000 lbs. was imported from France in 1847.

CART. The drag-cart without wheels, which is used in some mountainous districts, is one of the simplest contrivances for transporting heavy weights. It consists of two strong poles, connected by cross-pieces fixed at right angles to them, the ends resting on the ground. The other ends of the poles form the shafts for the horse to draw by. The Irish car may be considered as the next step towards a better construction. This car consists of a bed or platform and two shafts. The wheels, in the simplest form, are round disks of wood, fixed on a square axle of wood at the distance of three or four feet from each other. To the under part of the bed of the cart two blocks of wood are fixed, which raise it so that the wheels may go under the cart, and in these blocks are two round holes to admit the ends of the axle. This is the simple old Irish car. The only difference in the construction of the most improved modern cars is the substitution of neat wheels and iron axles for those described above, and a railing or box fixed on the platform.

The common cart differs from the car in that the body rests on a fixed axle between the wheels, which turn upon the axle by means of boxes in the centre of the naves. The simplest cart is that used by carriers in France and Germany. It consists of two strong poles of ash or beech, resembling those of the drag-cart described above. One end forms the shafts, and the whole is equally poised on the axle. The wheels are often nearly six feet in diameter, and narrow at the tire; they are slightly dished, but run nearly perpendicularly to the road. On these carts very great weights are transported, so as to require five or six horses to draw them. Where the roads are level and hard, waggons are much to be preferred to carts; but in hilly countries and bad roads carts have many advantages. For agricultural purposes various kinds of carts have been invented. The capacious tumbril for carting earth and dung, with broad wheels to prevent their sinking in soft ground, is too generally known to require description. The light Scotch cart, drawn by one horse, is justly considered as the most advantageous for transporting earth, lime, or dung, especially in hilly countries. It is low and short, so that the horse draws very near the centre of gravity; and there is little power lost by obliquity. It is made to carry hay and straw by means of a light frame, which is laid on it, and projects over the body and the wheels in every direction.

To avoid the weight resting on the back of the horse, carts have been invented with three wheels, the small additional wheel being made to turn in front. The addition of springs to carts and waggons is a very great improvement, and should be adopted in every case where they are much used on the roads. The additional weight of the springs and their cost are greatly overbalanced by their advantage: they lessen the draught, and, by preventing jolting and shaking, add to the durability of the vehicles.

Our agricultural machine makers have made many improvements in carts within the last few years. Croskill's one-horse cart is formed to carry a considerable load, with less weight on the horse than ordinary carts; it is now much used in agricultural counties, to carry (say) five quarters of wheat 10 or 12 miles to market and return with a solid load of 30 cwt. Among other varieties are the Norwich cart, the Norwich pair-horse waggon, the Exeter cart, the Scotch cart, the Newcastle cart, &c. Many of these carts are now provided with Croskill's patent wheels and axles, made wholly by machinery, and consisting principally of iron.

CARTHAMIN and CARTHAMEIN. The yellow colouring matter of carthamus is to be extracted by water, and it is then to be sprinkled with a very dilute solution of carbonate of soda, which dissolves the carthamin; this is to be precipitated by a salt of lead, and the oxide of lead separated by hydrosulphuric acid. By this treatment a yellow solution is obtained, which by spontaneous evaporation yields small prismatic crystals of pure *carthamin*. When exposed over mercury to oxygen gas, it becomes after some days merely yellowish; but, if a little alkali be added to it, it becomes immediately yellow, and then passes rapidly to a rose colour, which is employed by dyers as the source of some of the more delicate rose colours and the rich scarlet called *ponceau*. It also constitutes the basis of the cosmetic known by the name of *rouge*. The acids, and particularly citric acid, precipitate it from the alkali in the state of the well-known fine rose colour, which is called by M. Preisser *carthamein*.

CARTOON, is a word used by artists to signify the full-sized drawings or studies made in chalks, or body colour (*tempera*, as it is called in Italy), preparatory to executing any great work either in oil colour or fresco. Cartoons are also made when the design is to be copied in tapestry. The great masters seldom commenced any extensive picture without first making studies or cartoons in *chiaro'scuro*. Many of those by Raffaelle, Andrea Mantegna, Domenichino, the Caracci, and others, remain to attest the laborious diligence and care with which their great works were accomplished. By this means the composition, drawing, expression, and light and shade, were all perfected before the colouring of the picture was attempted.

The finest specimens of cartoons that are known are those executed by Raffaelle d'Urbino, which were sent to Flanders, in the reign of Pope Leo X., to be copied in tapestry, in two sets. The tapestries (only shadows of Raffaelle's exquisite designs) were finished, and one set is now in Rome. The cartoons, originally twenty-five in number, were left neglected at Brussels, and most of them seem to have been lost or destroyed. A few, however, escaped this fate, and seven are now in England in the royal collection at Hampton Court. Their history ever since their arrival in England is eventful. They were bought in Flanders by Rubens for King Charles I. At the dispersion and sale of the royal collection, the cartoons were secured to the country by purchase, by Cromwell's particular command; at which time, we are told, the Triumphs of Julius Cæsar, by Andrea Mantegna (still preserved at Hampton Court) were valued at 2000*l*., while the cartoons of Raffaelle were estimated at only 300*l*. In the reign of Charles II. they were again consigned to neglect. They had been sent to Mortlake to be copied in tapestry, where they were seriously injured. William III. had them repaired, and built a gallery at Hampton Court for their reception. George III. removed them to Buckingham Palace, and subsequently to Windsor Castle. They were again removed to Hampton Court, where they now are.

The subjects of these seven Cartoons are as follow:—

1. Paul preaching at Athens.
2. Death of Ananias.
3. Elimas the Sorcerer.
4. Christ delivering the keys.
5. Sacrifice at Lystra.
6. Apostles healing the Sick.
7. Miraculous draught of Fishes.

CARTRIDGE, is a cylindrical case containing a charge of gunpowder or shot, or of powder and ball, for fire-arms. Those used for loading muskets, carbines, and pistols, are formed of paper, and are styled ball or blank cartridges according as they contain both powder and ball, or powder only; while the larger cartridges for cannon and mortars, which always consist of powder only, are usually cased with flannel, though sometimes pasteboard, tin, or even wood, is employed. The North Americans, during their last war with England, are said to have employed very thin sheets of lead, resembling those used for lining tea-chests, for this purpose, thereby avoiding the danger of burning fragments of the cartridge-case remaining in the piece after firing.

Wire cartridges, for containing a charge of small shot, without powder, have been introduced for sporting purposes within the last few years. They consist of an inner case of wire network inclosed in a thin paper case, to the outer end of which a wadding is attached. The shot, with which it is usual to mix bone-dust or some other substance to fill up the interstices, is put within this case, which is rammed down upon the charge of powder. When the gun is fired, the paper case is torn to pieces as soon as the cartridge leaves the gun, and the shot immediately begins to quit the cartridge by passing through the meshes of the iron net work, which is carried forward with the charge until it is quite empty, when it falls to the ground. By this contrivance the heating of the gun is avoided, and the recoil produced by the discharge is lessened, the charge leaving the barrel like a bullet. The shot are also carried so much more closely than when loose, that lighter charges, and consequently a lighter gun, may be used; much time is saved in loading, especially as no separate wadding is required; and, as the cartridge has no inclination to move before it is impelled by the explosion of the powder, the danger arising from the accidental shifting or rising of loose charges is avoided.

Mr. Berney patented a few years ago a new kind of cartridge. The shot is enclosed in a spiral wire case, tapered towards the end, and provided with a cushion at bottom of wool, moss, tow, or any other soft elastic substance, to prevent by its elasticity the sudden explosion of the powder from breaking the case or jamming the shot. The case expands after its discharge from the gun, and according as the coils are more or less apart, so does the distance vary to which the bulk of the shot may be carried before escaping through the coils. The object intended by this cartridge is to convey a greater number of shot to a given mark, without diverging or separating, than can be done by the use of the ordinary cartridges; and experiments made near Chalk Farm in 1840, with this object in view, seem to have borne out the intention of the patentee.

Another new form of cartridge was patented in 1840 by Mr. Bush. It is made by taking a circular disc of wood, or two card-board boxes, like two pill-box lids fitted one within the other, having a hole in the centre in which a percussion cap is placed, and held there by being covered with a piece of calico or canvas.

Around this as a base the paper cylinder or case is formed and filled up with the proper charge of gunpowder, and shots or a ball as the case may be. This invention is intended to be used in conjunction with a peculiar mode of constructing muskets so as to be loaded at the breech.

Dr. Jager invented a new kind of cartridge in 1847, intended to be used with a new kind of musket also invented by him. There is neither priming nor percussion cap needed in the firing; but a kind of percussion cap, or nipple filled with fulminating powder, is formed in the cartridge itself; and the gun is so formed, that a small hammer, moved by the trigger, strikes on the nipple, which projects a little way into an aperture in the side of the gun.

From a return presented to the Committee of the House of Commons on the Ordnance Estimates, in 1849, it appears that the store of cartridges kept on hand by the Ordnance is immense. On the 1st January, 1849, the store in the United Kingdom and the colonies was as follows:—

Musket Ball Cartridges . . .	48,727,366
„ Blank „ . . .	8,527,159
Carbine Ball „ . . .	8,188,288
„ Blank „ . . .	4,335,087
Pistol Ball „ . . .	4,077,722
„ Blank „ . . .	946,023
Rifle Ball „ . . .	3,802,584
Musketoon Ball „ . . .	58,326
	78,662,555

When percussion muskets were introduced into the army, the old cartridges became useless. Most of the cartridges are made up by boys, in the Royal Laboratory at Woolwich; there are about 180 boys so employed, each of whom can make 600 ball cartridges or 900 blank cartridges in a day; but sometimes artillery men make them up in the colonies from powder sent from England in barrels.

CARTWRIGHT, EDMUND, though a graduate and a clergyman, comes before us for notice here as a mechanical inventor. In the year 1784 his attention was accidentally called to the subject of mechanical weaving. Dr. Cartwright's attention had never been directed to mechanical inventions, but by the April of 1785 he was enabled to produce his first power-loom, which, though an extremely rude machine, soon received many valuable improvements. Its first introduction was opposed both by manufacturers and their workmen, owing to various prejudices; and a mill containing 500 of his looms, the first which had been erected, was wilfully burnt down. With various improvements however it continued to force its way into use. In April 1790, Dr. Cartwright took out a patent for combing wool; altogether he obtained ten different patents for inventions and improvements of various kinds. In 1809 Parliament granted to Dr. Cartwright, who had hitherto derived little advantage from his inventions, the sum of 10,000*l.* for 'the good service he had rendered the public by his invention of weaving.' This was less than he had expended on his projects, but it enabled him to pass the remainder of his days in ease and comfort. He died in 1823, in his 81st year.

CARVING is usually understood to refer exclusively to works in ivory or wood, to distinguish it from carving in marble or stone, which comes under the term *sculpture;* or in metals, when it is called *chasing.* The ancients used ivory to a great extent in works of art, and its union with gold, called by the Greeks *chrys-elephantine* sculpture, was adopted by the greatest artists. In later times carving in ivory has been confined to smaller objects. Wood of almost every description was a favourite material for carving among the ancients, and, after clay, was doubtless, from the facility of cutting it, the first substance used for imitative art.

For a long period in modern times, there was a great demand for fine wood-carvings. The elaborately worked Gothic screens, choir seats, and desks, in most of our cathedrals and colleges, canopies, frames for doors and pictures, cabinets, and indeed every description of furniture, are evidences of the extent to which it was employed, and of the skill of the artists. One of the most eminent modern carvers in wood was Grinling Gibbons, a native of England. In London, the choir of St. Paul's may be instanced as a work of this artist. The German and Flemish carvers in ivory and wood were also much distinguished.

In Jordan's carving machinery, now at work at Messrs. Taylor, Williams and Jordan's establishment in the Belvedere Road, the wood has movement given to it, while the tools remain nearly stationary. A pattern of the work to be carved is first modelled by the artist, and afterwards copied by the machine in wood with perfect accuracy, and in such a manner that two or three copies are made simultaneously; the carving thus prepared by the machine is then sent back to the artist, who introduces by hand the finishing touches. A very large amount of the carving in the new Houses of Parliament has been effected by this machine. The more delicate work for the same building requiring hand-processes, is entrusted to Mr. Rogers, whose exquisite productions have done much towards the revival of a taste for this art.

About five years ago Mr. Pratt patented a carving machine, which was based on another patent machine, invented by Mr. Irving, for preparing the materials for inlaying. According to a description given of it before the Institute of British Architects, Mr. Pratt's Machine combines the principle of the lathe, the drill, and the pantograph. The material on which the design is to be carved is fixed on a table which turns on a centre. The tool, acting in the manner of a centre-bit, is attached to an arm, also working on a centre, and is made to revolve with great velocity. Guided by a pattern of cast-iron, the tool, by a double movement of the arm and the table, can be made to pass through any combination of curves, drilling out the material as it passes over it. The lines of the design are determined by the iron pattern, and the depth and form of the sinking by the shape and position of the tool; and if a double moulding is required, two patterns and two tools and a double operation are necessary. The tool and its position at the end of the arm being once adapted to the section of the moulding to be produced, the rest is purely mechanical; the workman guides the tool with one hand, and the table with the other, and the design comes out with great rapidity. The tool revolves three thousand times in a minute; and the wood is cut away in the form of very fine fragments, like sawdust, leaving a smooth surface behind it. The machine will cut stone with nearly the same facility as wood.

A kind of imitative carving was introduced a few years ago, in which a hot iron is employed instead of a cutting tool. An iron mould is prepared corresponding to the pattern to be produced; and this mould, being heated to redness, is applied with great force to the surface of a piece of damped wood; and this process is repeated until the required form is produced, by burning away the surface of the wood. The char is then removed; and any requisite undercutting is done by hand. When finished, the work has somewhat the appearance of old oak; and the surface may be brought to a high polish.

The recent exhibitions of manufactures, both modern and mediæval, have been rich in specimens of carving, showing to how high a degree of excellence this art may be carried. It is a pleasing feature in the history of taste that this art, after a long period of decline, has now again worked itself into favour.

CARYA'TIDES, female figures employed in architecture in place of columns. Like many other forms of art, they were most probably drawn from Egypt. Six beautiful Caryatid figures were employed in the Pandrosion, one of the buildings on the Acropolis of Athens. The northern portico of the Pandrosion had six Ionic columns, four in front, and one on each flank: the southern portico was supported by six Caryatid figures, four in front, and one on each flank. They were placed upon a basement, and supported an enriched entablature. One of the figures is now in the British Museum, among the Elgin collection. The execution of this figure is very fine; its height is 7 feet 9 inches. Caryatides may be seen at the side porches of St. Pancras Church.

CARYO'TA, a genus of palms which grows in tropical Asia. Its wood is so hard as to be cut with some difficulty, and is consequently of considerable value, provided the soft sapwood in the centre is scraped away. Roxburgh describes the tree as being highly valuable to the natives of the countries where it grows in plenty: it yields them, during the hot season, an immense quantity of toddy, or palm-wine. The pith, or farinaceous part, of the trunk of old trees is said to be equal to the best sago; the natives make it into bread, and boil it into thick gruel.

CASAN is one of the busiest cities of European Russia. It has a great cloth manufactory, in which 1000 work-people are employed. Cottons, morocco and other leather, soap, steel, iron, and earthenware, tiles, gunpowder, spirits, and beer are the other chief manufactures. It carries on an extensive trade by means of the Volga in these products, and in tea and other Asiatic imports.

CASE-HARDENING. This is a process by which the surface of a piece of iron has a quality imparted to it very much allied to that of steel; so as to superadd the hardness of a steel surface to the toughness of an iron foundation. It is applied to various kinds of tools and utensils; and is brought about by the action of heat and charcoal, as in the conversion of steel. [Steel Manufacture.]

CASE-SHOT are bullets contained in a cylindrical tin canister, or in a spherical shell of iron, which are discharged from a piece of ordnance. The first of these kinds of cases burst immediately on leaving the gun, and the bullets, which at first take diverging rectilinear directions, soon lose all regularity of motion; their effective range does not exceed 500 yards. The spherical case-shot, which were formerly called Shrapnell's Shells from the name of the inventor, are fired like common shells, and, the length of the fuse being properly regulated, they only burst at the required spot; consequently the scattered balls and the fragments of the shell may be made to take full effect in a column of an enemy's troops at 800 or 1200 yards' distance.

CASEIN is the basis of the various kinds of cheese, and closely resembles albumen in many properties. It is a curdy white substance, insoluble in water or alcohol, but soluble by water containing an alkali or its carbonate. It is coagulable, and is separated from the milk in making cheese.

CASEMATE, is a vault of stone or brickwork, frequently built in the thickness of the rampart of a fortress for the reception of artillery which is to fire through embrasures pierced for the purpose in the front of the vault.

CASHMERE. This very interesting mountain region of India has produce and manufactures of a peculiar character. The lower classes live partly on the *singhara*, or water-tun, which, during eight or nine months in the year, is fished from the bottom of the lake Wulur. Of this article, 60,000 tons are procured annually, sufficient for the support of 20,000 persons. The mucilaginous pith of the water-lily also supports a considerable number of people during eight months. Among the cultivated plants the crocus is the only one which furnishes an article of export, the saffron of Cashmere being known in all parts of Western Asia. A sort of grape, called *sun-gut*, yields, by distillation, a beverage which, in the opinion of the Chinese, is not inferior to that of the ordinary grape. Common grapes also abound, and the wine which is made resembles Madeira. No trees are cultivated with any care except the walnut, of which there are three different kinds; the kernel is eaten, and used for making oil; and the husks of the fruit are employed in dyeing black. Cashmere is famous for its flowers, especially roses, which are cultivated with care, and from them *attar* is extracted. [ATTAR OF ROSES.] Bees are very numerous, and each farmer has several bee-hives in the walls of his house,—sometimes as many as ten; these hives are of a cylindrical form, and extend quite through the wall. Silk-worms are reared, but less than formerly, when silk was an article of export. The metals are iron, which is abundant, copper, plumbago, and lead exist, but are not worked.

The Cashmerians are very industrious, which is shown in the excellence of their cultivation, and the perfection which their manufactures have attained. The principal branch of industry is shawl-making, in which 60,000 individuals are employed, though the number of looms, which two hundred years ago amounted to 40,000, has been greatly reduced. Two weavers work at each loom, when the shawls are simple; but when they are of a superior kind, four persons are required. According to one authority, 80,000 shawls are annually made, but the number is constantly fluctuating, so that no correct estimate can possibly be formed. Paper is also manufactured, and though less is now exported than formerly, it is still considered as the best made in Western Asia. The Cashmerians work with great skill and taste different objects in wood, which, as well as lacker-work, are exported to the neighbouring countries. The commerce of the country seems to be limited to the exportation of the manufactured goods, and the importation of wool from Tibet, and of metals from India, and perhaps from Persia. The transport of goods over the high mountains is chiefly effected by men, who carry them on their backs. Between Cashmere and Ladak sheep are used to carry burdens.

CASHMERE, is a peculiar textile fabric formed of the fine downy wool found about the roots of the hair of the Tibet goat, and so called from the original seat of the manufacture, in the valley of Cashmere. Shawls of exceedingly delicate quality are the principal articles manufactured of this material; but a cloth woven in imitation of them is also made, and called by the same name, or by corruption, Cassimere. *Kerseymere*, which resembles cassimere in sound, is a different fabric. [WOOLLEN AND WORSTED MANUFACTURES.]

An interesting description of the manufacture of Cashmere shawls is given in 'Vigne's Travels in Kashmir.' The process is exceedingly slow, the weaving of a pair of shawls, or, as some writers have it, of a single shawl, often employing three men with a clumsy old-fashioned loom for a period of six months; and, owing to the numerous heavy duties charged upon the shawls between leaving the loom and reaching a purchaser in this country, the price of real Cashmere shawls of the best quality is very high. They have frequently been sold in London at from 100 to 400 guineas each, and at one time, when the import duty, which has since been greatly reduced, amounted to 80 per cent. on the value, as much as 500 guineas has been demanded for a single shawl.

Various attempts have been made to naturalise the Cashmere shawl goat in this and other European countries; but, as the peculiarities of its wool appear to be dependent upon climate, the perfect success of any such attempt is problematical. The wool itself has also been imported as a raw material. In 1830, at which time the weaving of shawls from Cashmere yarn imported from France, had become an important branch of manufacture, a premium of 300*l*. was offered by the

Board of Trustees for the Encouragement of Arts and Manufactures in Scotland, to the person who should first establish the spinning of Cashmere wool upon the French principle. In consequence of this offer, Captain C. S. Cochrane devoted himself to the subject, and having succeeded, after some difficulty, in obtaining a knowledge of the secret, he patented the plan, and subsequently sold his patent to the Messrs. Holdsworth, of Glasgow, who established the manufacture successfully, and obtained the offered reward in 1832.

CASKS; COOPERAGE. The making of casks, barrels, butts, hogsheads, tubs, &c., is, up to the present time, almost wholly a handicraft employment. The peculiar shaping of the pieces of wood, the fitting them together, and the mode of binding them with iron hoops, —are all effected without the aid of anything which deserves the name of machinery. Yet when we consider how mathematically exact all the angles and curves must be, it would seem to be a branch of manufacture peculiarly fitted for the application of machinery.

Accordingly, we find that patents are frequently taken out for cask-making machinery. One such patent, by Mr. Brown, obtained twenty or thirty years ago, relates to a system of machinery, of which one part cuts the edges of the staves; another part cuts the groove or chine for receiving the head; a third part cuts the head into a circular shape: a fourth bevels the edge of the head; and a fifth gives a smooth circular surface to the exterior of the cask.

Davison and Symington's patent respecting casks, taken out in 1844, relates to the value of a rapid current of heated air, not only in drying wood, but in removing fungous impurities which often accompany damp-wood. They recommend that, in making a cask, instead of drying the wood in the ordinary way before using, by which it is difficult to bend without blistering, it should be cut up quite green, and shaped into staves and heads—due allowance being made for shrinkage. The pieces are easily bent in this state; and being temporarily fastened together, they are exposed to a rapid current of heated air, which carries off all the moisture, and shrinks the pieces to the proper size.

The same patentees also use hot air to cleanse casks after using: a method which they consider to be more effectual and cheaper than the use of steam, which is ordinarily employed in the great breweries. In order to remove from the interior of the cask any fungus or impurity which cannot be removed by the heated air, the patentees use a peculiar kind of chain, which enters at the bung-hole, and is worked about by means of machinery.

Mr. Robertson, a cooper of Liverpool, took out a patent in 1849 for a series of machines of rather complicated character, for making casks and similar vessels. One piece of apparatus is intended to plane, at one time, both sides of the staves which are to form the curved part of the cask; giving a convexity to one surface and a concavity to the other surface of each piece of wood. A second piece of apparatus planes the edges of the staves, giving to each edge the particular slope necessary for the staves to assume a circular arrangement when placed edge to edge. A third machine compresses all the staves together in a circular form, and forces the ends within the hoops which are to bind them together. Another machine presses together the pieces of wood which are to form the head of the cask, cuts them into a circular form, and bevels the edges. A fifth piece of apparatus cuts the groove in which the head is fitted to the cask; and another punches the holes in the iron hoops. Thus, according to the patentee's plans, every part of a cask is made by machinery.

Mr. Samuel Brown patented in 1840 a mode of making metallic casks. The cask is formed of a parallelogram of sheet iron or other metal, turned up into a cylindrical form, with an ordinary lap joint. The head of the cask is formed of a circular piece of metal, cut out and turned up all round the edge; this being forcibly driven into the cylindrical barrel, has rivets placed at intervals of four or five inches all round, which are rivetted through the barrel and through the turned up edge of the head. The other end of the cask, called the moveable head, is made like the first, but attached in a different manner; in this case projecting ears of metal are rivetted at proper intervals around the cylinder; and the heads of these rivets being within the cylinder, serve as stops to prevent the head of the cask from being driven in too far. This second head being forced into its place, the ears are bent down upon the edge of the cylinder and over the raised edge of the head, thereby retaining it firmly in its place. The joints are to be made fluid-tight with any of the ordinary paints or cements.

CASPIAN SEA. The depth of this inland sea in some places reaches to 600 feet; but, as the sea is mostly shallow near the coasts, it is unfavourable for navigation by large ships. The water is salt, but less so than that of the ocean. The navigation is confined to the countries lying on the west shores between the mouth of the Volga and the town of Asterabad. The Russians of Astrakhan use brigs of from 150 to 200 tons; but the Persians only small vessels, from 50 to 70 tons. The fisheries give employment to the inhabitants of the adjacent countries, who capture vast numbers of sturgeon, belugas, sterlets, salmon, and seals. On the shores, much naphtha is met with.

CASSA'VA, or Manioc, a nutritious fecula obtained from the roots of Jatropha or Janipha Manihot, and some allied species. This plant abounds in a highly poisonous juice, very small doses of which produce the most dangerous consequences; it is however of so volatile a nature as to be entirely driven off by heat, and consequently there is no practical difficulty in procuring the nutritious substance in a pure state. In order to effect this the roots are peeled, well washed, and then ground between millstones till they are reduced to a state of paste. This is subjected to pressure for the purpose of depriving it, as far as possible, of the juice; the residue is placed in vessels over a brisk and regular fire, and continually stirred, until it becomes dry; it then acquires a granular appearance, is gradually cooled, and afterwards packed in barrels, when it may be preserved for a great length of time. *Tapioca* is a preparation of Cassava.

CA'SSIA, is a genus of leguminous plants, consisting of a large number of species, chiefly inhabiting the tropical or temperate parts of the world, and including among them the plants that produce the *Senna* leaves of the apothecaries.

Cassia fistula is a small tree, with large yellow flowers growing in long loose racemes, having the aspect of a laburnum, and is found wild in India and the tropical parts of Africa. The leaves, flowers and pulp of this plant are purgative, but they are not now much used. *Cassia acutifolia*, a small under shrub, is found wild in Egypt, Sennaar, and Abyssinia, and forms an important article in the commerce of those countries. It is chiefly sent to Alexandria for shipment, whence it has gained the name of *Alexandrian Senna* among the drug-merchants. It is considered the most valuable of all the sennas. *Cassia lanceolata* is found wild in Arabia, whence it is exported under the name of *Senna of Mecca*.

Of the species of Cassia mentioned above either the pulp or leaves are used in medicine.

The quantity of Cassia imported in 1849, amounted to no less than 472,693 lbs.; and in six months, from April to October 1850, to the enormous quantity of 940,395 lbs.

CASSIA BUDS. The unexpanded flowers of a species of *Cinnamomum*, when they have attained about a fourth of their complete size, are collected and sold under this name. The taste and odour resemble cinnamon, and they are used for similar purposes. By distillation they yield a heavy yellowish-coloured oil.

CASTILE. New and Old Castile are richly favoured provinces in Spain. The plains of New Castile are among the finest wheat districts in the world; in La Mancha and Toledo the annual produce of wheat amounts to about 2,000,000 quarters. The want of roads, canals, and navigable rivers, is however severely felt. Almost the only means of transport for all kinds of produce is by mule-back. The principal objects of cultivation besides wheat are saffron, oil, fruits, wines, hemp, silk, and *garbanzos*, a sort of pea much used for food. The province is rich in minerals; but mines of iron, salt, and quicksilver are the only ones worked. The manufactures are confined principally to articles of common use. The province contains three or four important towns which call for notice elsewhere. [ALMADEN; MADRID; TOLEDO.]

The other province, *Old* Castile, nearly resembles New Castile in general character. In the department of Santander the high lands contain fine pasturage, and in many places are covered with forests of chestnuts, oak, pine, and fir. A great deal of butter is made. Goats are very numerous. Iron of the best quality is obtained. In summer the mountain pastures of the sierras are frequented by countless numbers of migratory sheep, which remain here till the beginning of October, when they commence their return to Andalusia for the winter. The manufactures are confined to coarse woollens, cotton, linen, leather and glass. Though agriculture is in a very backward state in all the departments, yet a good deal of wheat is exported from the province. The chief sea-port, Santander, is a place of considerable commercial activity, and carries on an extensive trade with Cuba, to which it exports flour ground at the large mills in the neighbourhood. Wool is exported to England and other countries. The imports consist chiefly of colonial produce. San Ildefonso, on the northern slope of the Sierra de Guadarrama, is famous for its manufacture of glass.

CASTING. [FOUNDING.]

CASTLE, from the Latin *castellum*, a diminutive of *castrum*, an encampment, is a walled inclosure with a tower or towers, strongly constructed and intended as a place of safety. Numerous castles, many of which are in ruins, still remain in various parts of Great Britain, France, Germany, Italy, and in the East. The castles of England consist of those erected by the Romans; of British and Saxon castles erected previous to the Norman conquest, and Norman castles erected after it; and also of the more modern stone and brick castles, erected from about the reign of Edward I. to the time of Henry VII. The Roman castles in this country are numerous, and some of them still in very perfect condition, such as Burgh Castle and Richborough. The Saxons most probably adapted the Roman inclosures to their modes of defence, and it appears that they often raised a mound on one side of the walls, on which they erected a keep or citadel. Roman castles were probably sometimes formed on the sites of British works; and Saxon castle-building was probably borrowed from the Romanised Britons, who had acquired a taste and knowledge of the arts from the Romans.

Norman castles, as fortifications, are the strongest. They consisted of mounds and ditches, or moats, with walls on the mounds surmounted with battlements: the walls were also fortified at the top with small projecting towers called bastions. In the walls were entrance gate towers, with bridges either of stone or wood, which were made to draw up and down. The entrances were also guarded with thick doors and portcullises, or gates which dropped down through grooves at the side of the masonry. All apertures, except the gateway, were usually very small. Platforms were made behind the parapets. The gateway was sometimes defended by a barbican and also flanked by towers, as well as the outer walls. The keep was usually in or near the centre of the castle, and it had sometimes a chapel within it. Rochester Castle, which stands on a small eminence near the bridge over the Medway, is a fine example of a Norman castle.

William the Conqueror was a great builder of castles. Forty-nine castles are mentioned in Domesday Book, which notices Arundel as the only one named in the time of the Confessor. It is said that in the nineteen years of Stephen's reign 1115 castles were erected. Every feudal chieftain had his stronghold, round which his immediate retainers rallied, for the purpose of mutual defence or to annoy and plunder their neighbours. A very considerable number of old towns of Europe gradually arose around these baronial fortifications; and it is interesting to trace, in the history of many of these communities, the progress by which the town, originally a miserable dependence on the castle, gradually attained privileges, and charters, and wealth, and increased in strength and importance exactly in proportion as the owner of the fortress lost both, till finally the castle, from being neglected and deserted, was either levelled with the ground and furnished materials for house-building, or remained in ruins, an enduring monument of the slow but certain victory of the once subject townsmen over their lords.

CASTOR is a secretion formed within the body of the beaver. The secretion is at first in a liquid state about the consistence of syrup, but it ultimately becomes solid, losing some of its odour and activity. As met with in commerce it is of two kinds, the Russian, and Canadian or English, of which the Russian is the rarest and most esteemed: it is more carefully managed from the time of its excision, being first dried in smoke, and often wrapped in swine's bladder. The odour is peculiar, very penetrating and unpleasant; the taste is also peculiar, bitterish, somewhat acrid or aromatic, and enduring. *Castorine* may be obtained by boiling one part of castor in six of alcohol, and leaving the filtered liquid to cool, when it falls to the bottom. It is very combustible, and is neither acid nor alkaline; it has a copperish taste.

Castor is used to a considerable extent in medicine.

CASTOR-OIL is procured from the *Ricinus Communis*, or Castor-oil plant, which was known from very ancient times both to the Egyptians and to the Greeks. The native country of the *Ricinus communis* is unknown, though it is conjectured to be originally from Barbary. The entire plant is possessed of active properties, but the oil extracted from the seeds is only employed in Europe. The ancients administered the seeds entire, but their variable action, occasionally even producing fatal effects, led to their disuse, and the oil is of comparatively recent introduction. The seeds, of which three are found in each capsule, are about the size of a small bean. They were formerly known in the shops as *Semina Ricini*. Various procedures have been adopted to extract the oil, and these have much influence on its qualities in respect of colour, acridity, and freedom from rancidity. Both in India and America, whence the first supplies were brought, much heat was employed, and during the process a volatile principle was either liberated or produced, which was so irritating as to require the workmen to protect their faces by masks. Even in the present day some heat is used to obtain what is termed the *cold drawn* castor-oil, but it is quite unnecessary, and should always be avoided.

Castor-Oil of good quality is a thickish fluid, of a very pale yellow colour, almost limpid, with a slightly nauseous odour, and an oily taste, mild at first, but causing a feeling in the back of the throat, which is more or less intense in proportion to the freshness of the specimen. Old or badly-prepared oil is rancid and disagreeable. It can be solidified only by a very low temperature.

Castor Oil is a valuable and well-known medicine, of which considerable quantities are used. The quantity imported in 1848 was no less than 4588 cwts.

CASTRES, a town in the department of Tarn in France, is a place of great manufacturing industry; for their care and skill, and the finish given to their productions, its artisans are considered the best in the south of France. It is particularly celebrated for its fine wool-dyed cloths, called *cuirs de laine;* but all other sorts of woollen stuffs are manufactured, as well as linen, soap, leather, glue, and paper. There are also several bleaching, dyeing, and silk-weaving establishments, and iron and copper foundries. The commerce of the town is very considerable.

CATALONIA, one of the provinces of Spain, is deficient in corn and cattle, but a good deal of wine is produced. Other articles of produce are oil, hemp, nuts, almonds, fruits, silks, &c. The forests abound with cork-trees, the bark of which is a considerable article of commerce. Catalonia abounds in mineral wealth, coal, copper, lead, zinc, manganese, cobalt, nitre, salt, marble, &c., being found. It is the chief manufacturing province of Spain, the principal products being woollens, cottons, silks, lace, leather, paper, iron, brandy, and liqueurs. The coasts abound with fish. Since the loss of the Spanish American colonies the trade of Catalonia has greatly declined.

Besides Barcelona, the principal town, there are *Tortosa*, with its salt pits and quarries of jasper; *Tarragona*, with its manufactories of silks, trade by sea, and exports of oil, nuts, wine, brandy, cork, &c.; *Reus*, with its manufactories of brandy and liqueurs; *Manresa*, with its manufactures of silks and gunpowder. *Mataró* has manufactories of cottons, silks, lace, and glass, and ship-building yards. *Vich* has manufactories of woollens and cottons; coal and copper mines are worked in the neighbourhood, in which also are found amethysts, topazes, and coloured crystals, which are worked by the jewellers of Barcelona. *Ripoll* is north of Vich, and has manufactories of firelocks, swords, and bayonets.

CATAMARAN is a name given both in the East and West Indies to some kinds of rafts which are used in short navigations along the sea-shore. Those used at Madras, where the coast is shallow and shelving and the surf very great, consist of three cocoa-tree logs lashed together, and only large enough to carry one or at most two persons. On the coast of South America the rafts are from 70 to 80 feet long, and from 20 to 25 feet wide.

CATECHI'NUM. This peculiar principle is obtained not merely from Catechu, strictly so called, but also from gambir and some kinds of cinchona bark. The best mode of procuring it is to digest catechu in sulphuric æther, then evaporate the æther, wash the residuum in cold water, repeatedly dissolve it in boiling water, and by renewed evaporation procure it pure. It is persistent at the ordinary temperature of the air; but by long exposure to damp it resolves into a mould-like mass: at a moderate heat it melts into a transparent fluid; by a strong heat it becomes brown. Catechin is valuable as an application to check the flow of blood from leech-bites, scarification of the gums, &c.

CATECHU. [Acacia.]

CATENARY (from *catêna*, a chain) is the curve in which a string of perfect flexibility and uniform thickness and density will hang from two points, which we may suppose to be in the same horizontal line, as the nature and properties of the curve will be the same from whatever points it may hang. And all catenaries are similar curves; that is to say, let there be any number of such curves formed by chains of different lengths, then each of them will be a picture, on a reduced or enlarged scale, of some portion of the longest.

In Bridge-building, great attention is paid to the natural tendency of materials to assume a catenary curve under certain circumstances.

CATGUT. Several useful articles, manufactured from the intestines of the sheep, are for some explained reason denominated catgut. Catgut is generally in the form of cord, string, or twine. The chief purposes to which such cord is applied are musical strings, for harps, violins, and guitars; hatters' bowstrings, for the bowing of fur and wool; clockmakers' cord; and thongs or cords for whips. Goldbeaters' skin is formed from a membrane covering the intestine of the ox.

CATTLE. A few of the commercial features relating to cattle are all that need be touched on in this work.

The British and Irish breeds of cattle have been resolved into Long-horns, Middle-horns, and Short-horns. The *Long-horns* were formerly coarse and heavy beasts; they had, however, good points; the hide was thick and mellow, and the milk, though not abundant, was rich. The great improver of this breed was Mr. Robert Bakewell, of Dishley, who founded what was called the New Leicester or Dishley Stock. But of late years this breed has fallen behind the improved Short-horns;

and, though good Long-horned cattle may occasionally be seen in the midland counties, the fame of the New Leicesters is extinguished. To the *Middle-horned* race belong the breeds of Devonshire, Herefordshire, Gloucestershire, Sussex, Wales, and the Scottish Highlands. The horns are of moderate size, fine, well turned, and sharp pointed; the limbs are clean; the figure is compact, and the expression animated; the oxen readily fatten, and the cows yield rich milk. In hardiness, and in the excellence of the meat they yield, the Middle-horns claim a high rank. Devons, Herefords, and Scots, whether horned or polled, sell well in the London markets. The *Short-horns* had long been known in the counties of Durham and York, before the time of their great improver, Mr. Collings. The cows were held in reputation as milkers, but the oxen were indifferent feeders, coarse, and ill formed, and produced meat of inferior quality. In the improved breed, however, while the milking properties are preserved, the tendency to fatten is brought to a high degree; and these qualities are combined with size, a magnificent figure, and the production of beef of the highest excellence.

The present leading breeds are the Middle-horns, and the Durham, Yorkshire, and Tees-water improved Short-horns. It is from the latter stocks that the great London dairies are supplied with milch cows. While in milk they yield abundantly, and when dry may be fattened off for the market with rapidity.

The great day for the sale of cattle in London is on the Monday in the week before Christmas. On this day, in six following years, the numbers brought to Smithfield have been as follows:—

1845	..	..	5320
1846	..	..	5470
1847	..	..	4250
1848	..	..	5940
1849	..	..	5758
1850	..	..	6720

The cattle exhibited for prizes at the Smithfield Cattle Show increased in number from 83 in 1845 to 180 in 1850.

The foreign cattle (including calves), imported into the ports of London and Hull, in forty-six weeks of the year 1850, amounted to 51,572.

The cattle sold at Smithfield amount at the present time to about 220,000 annually.

Of the uses which cattle render to the arts of life, in respect to milk, butter, cheese, leather, bladder, gold-beater's skin, horn, blood for clarifying, bone for handles and for manure, &c., the details given in this work afford much evidence.

CAVIAR, an article of food, which consists of the roes of large fish, salted and dried, especially of the sturgeon caught in the Volga. Large quantities are made in the neighbourhood of Astrakhan, as many as 30,000 casks having been exported from that city in a single season.

CAXTON, WILLIAM, to whom England owes the introduction of printing, was born probably in 1412, in the Weald of Kent. He was put apprentice to one Robert Large, a mercer or merchant of considerable eminence; and afterwards he travelled in the Low Countries for a short time. In 1471 Caxton describes himself as leading a life of ease, when, 'having no great charge or occupation,' he set about finishing the translation of Raoul le Fevre's 'Recueil des Histoires de Troye,' which he had commenced two years before. The original was the first book he printed, and this translation the third. In the Low Countries he entered into the service, or at least the household, of Margaret, duchess of Burgundy, who encouraged him to finish his translation of Le Fevre's 'History of Troy.' From the prologues and epilogues of this work we discover that he was now somewhat advanced in years, and that he had learnt to exercise the art of printing; but by what steps he had acquired this knowledge cannot be discovered; his types, however, show that he acquired it in the Low Countries. The time of his return to his native country is not known with certainty; but the usual supposition has been that he brought the art of printing into England in 1474. In 1477 he had undoubtedly quitted the Low Countries, and had taken up his residence in the vicinity of Westminster Abbey, where and in which year he printed his 'Dictes and Sayings of the Philosophers.' Stowe says he first exercised his business in an old chapel near the entrance of the Abbey; but a very curious placard, a copy of which, in Caxton's largest type, is now at Oxford in the late Mr. Douce's library, shows that he printed in the Almonry. His death took place in 1491 or 1492.

Caxton, Mr. Warton observes, by translating, or procuring to be translated, a great number of books from the French, greatly contributed to promote the state of literature in England. The known productions of his press amount to 64, and are enumerated with their titles in the 'Penny Cyclopædia.' Lists are also given by Dibdin, Lewis, and others.

The two largest assemblages of the productions from Caxton's press now known are those in the British Museum and in Earl Spencer's library at Althorpe.

CAYENNE PEPPER, is capsicum in a ground state. [CAPSICUM.]

CEDAR. The Cedar of Lebanon *(abies cedrus)* is described under ABIES, p. 6. The name of *Red Cedar* is sometimes given to the *Juniperus Bermudiana*, a tree from whose wood cedar pencils are made. About 1700 tons of this wood were imported in 1847.

CE'LEBES, a large island in the Eastern Seas, grows cotton, coffee, tobacco, and other merchantable produce. There are mines of iron, which yield metal of excellent quality, and some gold is obtained. Very large quantities of turtle are taken on the coast.

The population of Celebes is composed of several distinct races, of which the Bugis are considered to be the first in enterprise and intelligence; they engross nearly all the carrying trade of the Indian Archipelago, the trading of other tribes being almost entirely confined to coasting voyages.

CELLI'NI, BENVENUTO, born at Florence in 1500, was one who combined metallurgic skill with artistic genius to a degree perhaps never paralleled. His works may be divided into two classes. The first, for which he was most celebrated, comprises his smaller productions in metal, the embossed decorations of shields, cups, salvers, ornamented sword and dagger hilts, clasps, medals, and coins, in which he showed great skill in composition, and excellence in the details of execution. The second includes his large works, as a sculptor; and a reference to his bronze group of Perseus, with the head of Medusa, in the Piazza del Gran' Duca, in Florence, will be sufficient to illustrate his merit in the higher walk of his art. He also executed some fine portraits. His far-famed Shield of Achilles was displayed at the Mediæval Exhibition of 1850

CEMENT. Various cements are described under GLUE; LUTES; MASTICH; MORTAR; SOLDER. Another cement, used for fixing pieces of glass while being ground for optical purposes, is made of resin, bees' wax, and whiting. Metal chasers often use a cement made of pitch, resin, tallow and brickdust. A cement for alabaster or spar may be formed of resin, bees' wax, and plaster of Paris. For various purposes in the arts, the following are used as cements:—Shell-lac; melted sulphur; a mixture of lime and white of egg; a mixture of gum arabic, gum ammoniac, and alcohol; gum ammoniac, isinglass, and alcohol; rice paste; sal ammoniac, flowers of sulphur, and iron filings; red lead, white lead, and linseed oil; quicklime and ox-blood.

Benson's metallic cement is a mixture of blue lias lime with a sort of metallic sand very much like the Italian *puzzuolano*, but containing rather more iron. It is very durable both as a concrete and as a cement. It has been used at the Houses of Parliament, at the London Bridge Station, at the Alfred Life Office, and at other large buildings—sometimes as a concrete for foundations, but more frequently as a stucco for surfaces.

The recipes given in practical works, for making cements, are exceedingly numerous.

Mr. Swindells, a manufacturing chemist of Manchester, has recently introduced a cement made from the refuse of the manufacture of chromates of potash and soda—useful for no other purpose.

CENSUS. The general subject of a census of population is beyond the scope of the present work; but we may give from the census of 1841, the number of persons engaged in productive industry, under the headings of commerce, trade, manufactures, agriculture, and unskilled labour, in Great Britain.

CLASSES.	ENGLAND.	WALES.	SCOTLAND	ISLES in the BRITISH SEAS.	GREAT. BRITAIN.
	Total of Persons.	Total of Persons.	Total of Persons.	Total of Persons.	Total of Persons.
Commerce, Trade, and Manufacture	2,529,073	90,133	473,581	17,589	3,110,376
Agriculture	1,157,816	103,632	229,337	8,493	1,499,278
Labourers	620,492	53,430	84,573	3,373	761,868
	4,307,381	247,195	787,491	29,455	5,371,522

The approaching census, to be made on March 30, 1851, will afford materials for a useful comparison with the above.

CENTIGRADE means divided into one hundred degrees. The centigrade thermometer of Celsius, which is much used on the continent, divides the interval between the freezing and boiling points into 100 degrees. Thus 100 centigrade degrees are equivalent to 180 of Fahrenheit.

CENTRE, CENTER. This word is used with many different applications, in manufactures and machines dependent on dynamics and statics:—*Centre of gravity* is the point at which, the weight of a body being collected, the equilibrium of the body and of the system, if any, of which it forms a part, will not be disturbed. *Centre of gyration* is the point at which, if the whole of the matter in a body were collected, given forces would produce the same angular velocity of rotation in a given time as they would do if the particles of the body were distributed in their proper places. *Centre of percussion* is that point of a revolving body which would strike an obstacle with the same force as if the whole of the matter were collected in it. *Centre of oscillation* is the point in which the whole of the matter must be collected, in order that the time of oscillation may be the same as when it is distributed. *Centre of pressure* is the point at which the whole amount of pressure may be applied with the same effect as it has when distributed.

CENTRIFUGAL FORCE. Centrifugal force is very usefully applied in the action of Drying Machines, and many other pieces of mechanism employed in manufactures. The nature of the force may be thus illustrated:— Let us suppose a small bullet attached to a string, which string is fastened to a point upon a table, friction and the resistance of the air not being supposed to exist. Let the bullet be placed in a state of revolution round the fixed point, by means of the string, and with a given velocity. It will continue to revolve round with the same velocity, and the string will be stretched by a pressure depending upon the mass of the bullet and its velocity.

This pressure of the string is caused by an effort to escape on the part of the bullet, arising from its tendency to continue its motion in the direction of the tangent. This is the *centrifugal* (or centre-avoiding) force, which is thus measured: suppose, for instance, the velocity of revolution in the circle to be 8 feet per second, and the radius 10 feet. Divide the square of the velocity by the radius, or divide 64 by 10, which gives 6.4. Then the pressure is such, that were it to take the place of the earth's attraction, the bullet, being allowed to fall, would, at the end of one second, have acquired a velocity of $6\frac{4}{10}$ feet per second, instead of $32\frac{1}{6}$, which is the case with bodies falling freely to the earth.

CERATES are mixtures made by druggists, in which wax is always a component. They are of a consistence between that of plasters and ointments, and are used as external applications in many surgical cases. There are not less than thirty different varieties of cerate employed by medical practitioners.

CERIUM, a peculiar metal, discovered in 1804, is pulverulent, chocolate-coloured, inflammable in gaseous chlorine and the vapour of sulphur. It decomposes water readily. When heated it burns long before redness. With oxygen and other simple substances it unites to form many compounds; but these are not yet much employed in the arts.

CETINE, is the cystallisable matter which forms the greater part of the substance called *spermaceti*. It is white, crystalline, soft to the touch, and friable; it is nearly inodorous, and tasteless; it fuses at 120° Fahr.

CEYLON. This fine island is particularly rich in natural produce; and preparations are being made to exhibit a most extensive collection of such produce at Hyde Park in the present year. Among the vegetable produce are cotton, tamarinds, gamboge, coir, cocoanuts, coffee, rice, nutmegs, ginger, mandioca, arrow-root, a great variety of vegetable fibres fitted for cordage, and a fair variety of timber wood. Of animal products there are being collected ivory, buffalo and deer horns, honey, wax, hides, hoofs, and musk. Among dye materials are madder, jack-wood, sapan-wood, and turmeric. The sea shores will yield pearls, mosses, sponge, cowries, and salt, minerals, medicinal substances, gums, and resins—are all in rich variety.

Mr. Capper, secretary to a committee for managing the transmission of specimens to England, in a letter to Lord Torrington, remarks: "Without placing the Cingalese carvers and workers in the fine metals, on an exact par with other nations famed for such works, they may yet be fairly entitled to an honourable place. The specimens now preparing of carvings in ebony, calamander, ivory, shells, &c. will, it is believed, earn a reputation for the island workmen, which has not yet been accorded them in England. The committee is doing all in its power to procure the best specimens of silver ornaments."

An important arrangement for Ceylon is that which makes it a central point for the Oriental Mail Packets. A mail which leaves Southampton every month, viâ Alexandria and the Red Sea, stops at Ceylon whence two branch mails issue, one to Madras and Calcutta, the other to Penang, Singapore, and Hong Kong; and it is probable that another branch mail to Australia, Van Diemen's Land, and New Zealand, will be made part of this monthly system—all conducted by steam navigation.

A good deal of weaving is carried on at Ceylon. The pressure of oil from numerous varieties of seed is also largely conducted. Ceylon takes British goods to the value of about a million sterling annually, and sells in return large quantities of cinnamon, coffee, and cocoa-nut oil.

CHAFF MACHINES. The machines for cutting chaff for cattle and horses present many varieties. At the recent Smithfield cattle show (1850) many forms were exhibited. Gillet's Guillotine Chaff Engine acts either by hand or by steam power; by hand it will cut 30 bushels per hour; by steam 200 bushels. It has a knife with two edges so as to cut both up and down during its motion, which is communicated by a crank. Samuelson's chaff cutter has a large wheel, rotated by a lever handle, and having a knife edge forming one radius to the wheel. Wedlake's machine is somewhat similar, but has two radial knives instead of one. The more common chaff-cutter or chaff box consists of an oblong box, in which the hay or straw is laid: and a long knife cuts the ends which protrude beyond the box; the knife has a double lever action, which assists the labour of the cutter. Messrs. Cottam's chaff-cutting machine, patented in 1849, is a complicated piece of apparatus in which the hay or straw is led between rollers to the spot where the cutters can act upon it.

CHAGRES. Under PANAMA is given a slight sketch of the important travelling routes across the American isthmus, of one of which Chagres is the Atlantic port.

CHAIN (in Surveying) is a measuring chain of 100 links, altogether 4 poles, or 66 feet, or 22 yards in length, so that ten square chains make an acre. It is commonly called Gunter's Chain, having been first used by him, and described in his treatise on the Cross Staff, &c.

The chain is of universal use in modern surveying; but care must be taken to verify its length from time to time, since the material is very extensible, and the apparatus must necessarily be roughly used.

CHAIN-CABLES are iron chains used in lieu of hemp cables for anchoring vessels. The liability of hemp cables to be destroyed by the alternate action of air and water, and especially by chafing in rocky anchorage ground, led M. Bougainville to suggest the idea of substituting iron as early as 1771; but the idea was not taken up till 1808, when Mr. Slater, a surgeon in the navy, obtained a patent for a chain-cable. Even after this many years elapsed before their advantages wree generally recognised. Chain cables are usually furnished with bolts at the distance of one or two fathoms from each other, by withdrawing one of which a ship may slip her anchor in case of emergency in less time than would be required to cut a hemp cable. The weight of a chain-cable is an advantage while the ship is at anchor, as the strain is exerted on the cable rather than on the ship, and must be excessive before it can draw the cable straight.

Mr. Frearson, of Birmingham, patented in 1848 a method of making chains (for cables and other purposes). The rod of iron is grasped while red-hot by tongs or pinchers, and drawn between two grooved rollers; these rollers have so peculiar a movement imparted to them by machinery, that the bar is forced round a die or mandril, into a form fitted to produce a link; while arrangements are at the same time made for connecting this link with the one last made.

A new cable-proving machine was introduced in 1848 by Messrs. Dunn and Elliot, of Manchester. It consists mainly of a horizontal iron cylinder, with a piston working to and fro. The chain-cable is attached to one end of the piston-rod; and beyond this rod is a long iron trough, in a right line with the cylinder, and continuing to a considerable length, depending on the length of chain to be tested at one time. At the remote end of this trough a pair of claws grasp the other end of the chain; so that the chain extends from the piston to the claws, through the cylinders and the trough; and any force which tends to move the piston backwards will stretch the chain. The end of the cylinder next the trough is made watertight; and water is forced by a double hydraulic pump into the hollow space between the piston and this closed end of the cylinder: the cylinder is thus forced backward, and the chain becomes severely stretched. A water ram and scale-beam are so placed in connection with the cylinder as to measure the amount of force exerted on the chain. The same machine can test strengths between the wide limits of ½ cwt. and 100 tons.

CHAIN-SHOT. Two iron balls linked together by a chain eight or ten inches long are so called. They are used in naval actions.

CHAIRS. It is a remarkable fact that the handsome chairs of a modern drawing-room are very little other in shape than fac-similes of the chairs made by the Etruscans twenty-five centuries ago. The chair of Bede, the Saxon bishop and historian, was simply a long narrow box without a lid, formed of rough boards, nailed together and set upright, with a shelf near the lower end as a seat. King Edmund Ironside had a gala chair formed of two carved beams of oak, crossed like the letter X, with a cushion-seat at the place where the beams crossed. The chair appears to have been more used in England than on the continent in past ages; for it did not come into customary use among the nobility of France and Italy till about the reign of Francis I.

In reference to chair making in London at the present time, a few details are given under FURNITURE MANUFACTURE.

Modern ingenuity has devised a mode of making chairs which shall also serve as sofas and bedsteads. A piece of furniture recently patented by Messrs. Key and Mitchell is of this kind. The *suspension* chair, patented by Messrs. Brown, is a remarkable contrivance consisting simply of eight wrought iron bars, and a piece of strong canvas or damask; although capable of forming either a chair or a sort of couch-bed, it can be unscrewed, and packed in a box 52 inches long by about 2 inches square.

CHALK forms the higher part of the geological series or group termed cretaceous. It is composed of nearly 44 parts of carbonic acid and 56 parts of lime. It is extensively used in agriculture, to improve various soils: the soils most improved being the strong wet clays which contain a portion of iron. Chalk acts as an absorbent, corrects astringency, and prevents clay from becoming a solid mass. On loose sands it acts chiefly as a cement, binding the silicious particles together. In districts where chalk is much used, it is generally put on the land in autumn, and not ploughed in till it has been exposed to the frost.

It is of advantage to throw chalk into ponds used by cattle: it corrects any acidity which may arise from stagnation. In fattening calves chalk is of great use; it may be laid in the calf-pens for them to lick, or it may be scraped and mixed with a small quantity of salt, and laid in a small manger within the reach of each calf.

Chalk is used in preparing crayons, and for a few other purposes in the arts.

CHAMOMILE. This useful plant is frequent in a wild state on many of the commons near London. The flowers are much used as a tonic.

CHAMPAGNE WINE is the produce of the vineyards of the departments of the Marne, Haute-Marne, Ardennes, and Aube, which were comprehended in the ancient French province of Champagne. Of the various growths of Champagne, that made on the banks of the Marne has the highest reputation, and forms the greater part of what is sent to foreign countries. Champagne wine is light in body: it is of various colours, white, straw-colour, pink, and red; and these are divided into sparkling, creaming, and still, or, as they are called in France, *mousseux*, *crémant*, and *non-mousseux*. The red wines of good quality are, for the most part, exported to Belgium, and the white to England, Russia, Germany, the Levant, Greece, and the French West India colonies; some portion of the shipments to England are reshipped to India and other parts. The details of the vintage are given under WINE.

CHAPTAL, JEAN ANTOINE, was one of those experimental chemists whose labours bring great and immediate aid to the manufacturing arts. He was born in 1750; and inheriting a large fortune from his uncle, he established some important chemical manufactories in Montpellier, and thus bestowed upon France several valuable products which were previously obtained from foreigners. In 1793 Chaptal was called to the capital by the Committee of Public Safety, to manage the manufactory of salt-petre, which substance could no longer be obtained from abroad, and the want of which was pressing. He was one of the first professors of the Polytechnic School, and in 1798 was elected a member of the Institute. While he was in office under Napoleon, he established chambers of commerce, and consulting councils of arts and manufactures; the School of Arts and the Conservatory at Paris are monuments of his enlightened solicitude for increasing the opportunities and means of instruction. He published useful processes, visited the manufactories, conversed with the workmen, offered them his advice, applauded their discoveries, and encouraged the importation of processes and apparatus from abroad. In fact, during the whole course of his active life, he extended his views and his care to every substance and circumstance which he considered favourable to the improvement of arts and manufactures. He died at Paris in 1832.

CHARCOAL. The relation which charcoal bears to carbon has been already explained. [CARBON]. As now conducted, charcoal is prepared by two different methods. One is that of piling the wood in a heap, which is covered with turfs and sand, to allow of the entrance of such a portion only of atmospheric air as is sufficient to carry on the imperfect combustion required. The heap is fired at several holes left near the bottom, and a draught of air is obtained by at first leaving an orifice at the top of the heap; this is afterwards covered, and, when it is found that the flame has prevaded the heap entirely, the bottom holes are also closed. In the other method, the wood is put into iron cylinders, which are set in brick-work, and surrounded by fire: the wood in the cylinders has no communication with the external air, and they have only a small opening to allow of the escape of the residual products, which consist chiefly of water, pyroligneous acid, creosote, pyroxylic spirit, and empyreumatic oil.

M. Violette communicated an important paper to the French Academy of Sciences in 1848, on the manufacture of charcoal for gunpowder. He found that when wood is exposed to heat in close vessels, it does not become charred till near 500° F., when it produces an imperfect charcoal; at near 600° it yields a brown charcoal; while the best black charcoal requires a temperature of nearly 700° F. He also invented a remarkable mode of making charcoal by the heat of steam. The wood is put into a horizontal cylinder, round which is coiled a steam-pipe, and through this pipe is sent a constant flow of steam of a determinate temperature, according as a greater or lesser degree of charring is required. M. Violette has found that fuel is saved, and better charcoal produced by this method; he has adopted it at the powder mills of Esquerdes, which are under his charge.

CHASING OF METALS. Metallic goods are generally made in one of three ways—by casting in moulds, by forging or turning in masses, or by pressing or stamping out of thin sheets. The last of these three has been greatly developed at Birmingham within the last few years. Either the entire article receives its form from the sheet by stamping, or, when roughly formed, it receives an ornamental device by a process of chasing. For the latter variety of work, steel blocks, punches, or bosses are provided, each one presenting at the end a definite form, such as curved, angular, square, &c.; and these are fixed or held with the finished end uppermost. The article to be ornamented, which is always of a thin, hollow kind, is placed face uppermost on the punch: a pattern or design is drawn on the face of the article, and the adjustment is so made that the punch beneath shall follow the course of the lines in the device. A fine hammer is then employed to strike the piece of thin metal; the effect of which is, that the metal is forced upwards in a fine burr or protuberance at every place where there is a punch beneath it. By shifting the piece of metal so that different parts of its lower surface may in succession be brought over the punch, and by changing the form of the punch when necessary, a protuberant design or pattern in relief is formed on the article of metal.

At the Mediæval Exhibition of 1850 the specimens of chased metal were numerous and beautiful.

CHATHAM ARSENAL. Chatham is worthy of our attention for the government works there established. The naval and military establishments consist of a dockyard, nearly a mile in length, which has four wet docks capable of receiving vessels of the largest size, and several building-slips; metal mills: an extensive arsenal; barracks on a large scale for artillery and engineers, infantry and royal marines; a park of artillery; magazines and storehouses; besides a handsome dock-chapel and a number of habitations for the civilians who are employed. The principal mast-house is 240 feet long by 120 feet wide. The rope house is 1,128 feet in length, and 47½ feet wide: in it cables 101 fathoms in length and 25 inches in circumference are made. The machinery used in all the departments is of the very best kind. A duplicate of Brunel's block-making machine is kept here, ready for use in case the machine at Portsmouth should get out of order. The engineer barracks are built in a plain and simple style, and are extensive and convenient. Near the dock-yard gate is a large naval hospital, which was erected at the suggestion of William IV. when lord high admiral.

In 1848 a committee of the House of Commons inquired into the navy estimates and the works and expenditure for which they were required. Chatham dock-yard was included among the naval establishments investigated. The estimates included salaries 17,459*l.*; and wages 101,300*l.* The authorised or established workmen were 1,727 in number, and the hired workmen 233. There were said, in the Report, to be four docks, viz.: two for first rates, and two for frigates; and nine slips, of which six were for first rates. After the fire at Devonport dock-yard in 1840, which was greatly extended owing to the tarred wooden and paper roofs which covered the building slips, the admiralty began gradually to replace such roofs with others made of metal. Of these three have been constructed for Chatham, and placed over the slips Nos. 1, 2, and 3, at a cost of 32,590*l.* Nearly all the slips have been recently either rebuilt or strengthened and repaired. The metal mills at Chatham are more extensive than at any other of the dock-yards. At the time of the inquiry (1848) the metal mills produced 700 tons of sheet copper, 400 tons of bolt copper, and 800 tons of remanufactured iron per annum. All the old copper sheeting from the various dock-yards is re-melted here into sheets.

There are saw-mills at Woolwich, Chatham, and Sheerness: but those at Chatham are the most complete. The Chatham mills could, indeed, it is said, cut timber enough for most of the yards. It is merely straight cutting: the machinery employed is not fitted for cutting the curved pieces required in a ship, which are still cut by hand.

CHECK, a species of chequered cloth, in which coloured lines or stripes cross each other rectangularly, like a chess-board. This manner of beautifying webs is very antient; for many of the figures in Rosellini's 'Egypt' are dressed in chequered cloths. The compartments of a checked pattern are sometimes formed by differently coloured threads, and sometimes by threads of different quality. Cotton handkerchiefs checked of various colours have been manufactured in India, probably from time immemorial, under the name of *pullicates*. The ground of these has usually a pale buff colour, and is woven with the nankin yellow cotton. Checks in this country are mostly manufactured for the coarser purposes of seamen's shirts, aprons, &c., and the demand is very large.

Mr. Robert Kay, of Bury, son of the ingenious but persecuted inventor of the fly shuttle, invented the drop box, for making checks, by means of which the weaver could at pleasure use any one of three shuttles without rising from his seat, each shuttle containing a differently coloured weft.

CHEESE. Milk consists of three distinct substances, which begin to separate from one another as soon as it is exposed to the air. The oily part rises to the surface by its less specific gravity, and, when it is collected into a solid mass by agitation, it forms *butter*; the caseum coagulated by the action of any acid is called *curd*, and when pressed becomes *cheese*. The fluid which remains is the serum, or *whey*.

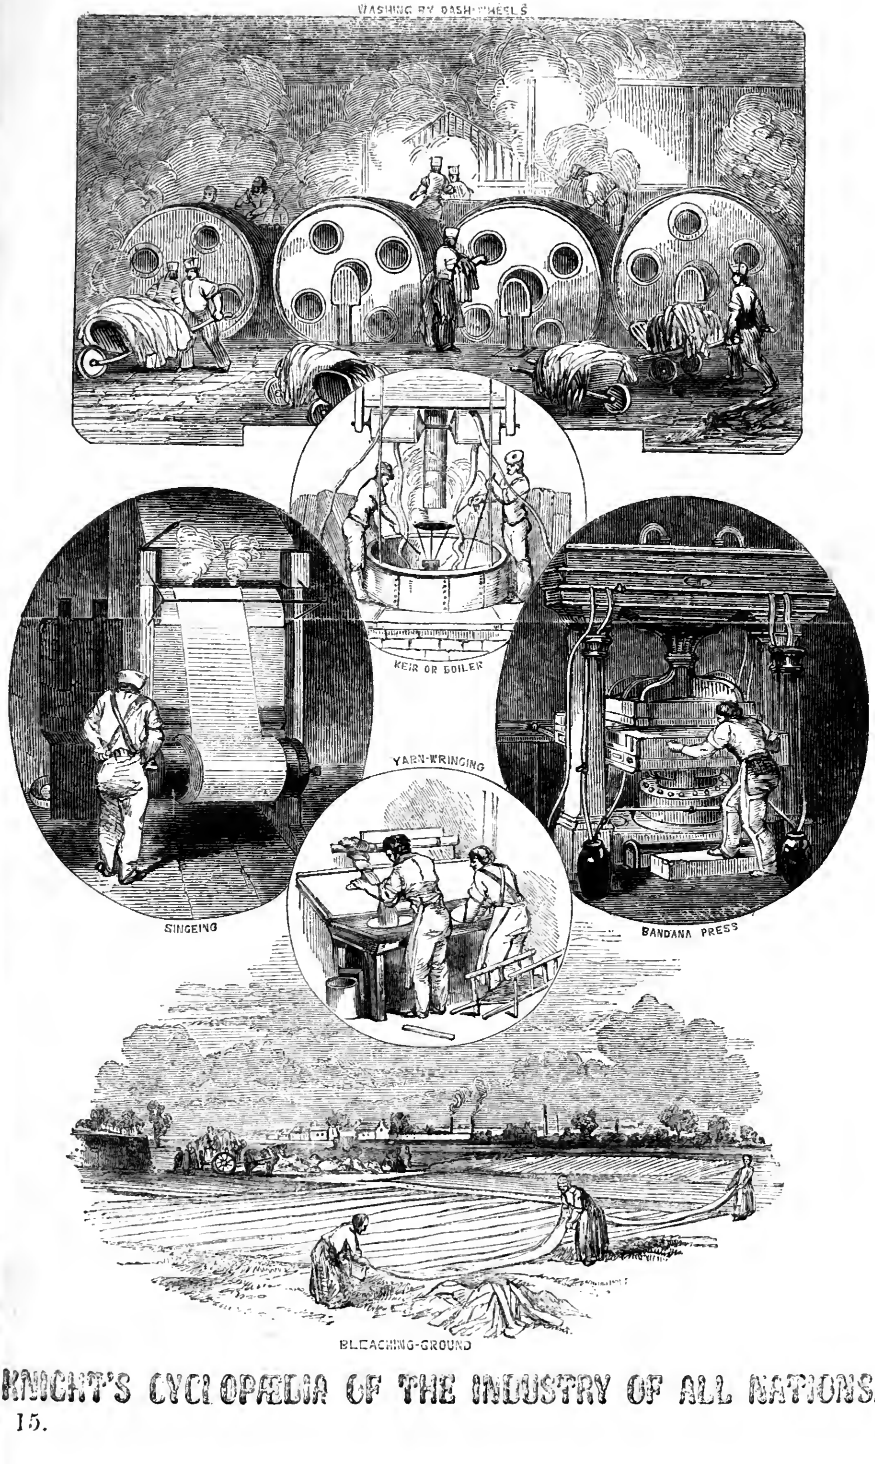
The first process in making cheese is to separate the curd from the whey, which may be done by allowing the milk to become sour; but it is better to bring about this result by artificial means, by the addition either of certain vegetable acids, or of a substance called *rennet*, which is the gastric juice of the stomach of a sucking calf. The calf stomach is very carefully prepared, and brought to a dry state like parchment; and at the time of making cheese, a piece of this substance, called *vell*, is cut off and soaked for some hours in water or whey, and the whole is added to the warm milk, or else pieces of vell are put into a linen bag, and soaked in warm water until the water has acquired sufficient strength. Soft and rich cheeses are not intended to be kept long; hard and dry cheeses are adapted to be kept and stored for provisions. Of the first kind are all cream cheeses, and those soft cheeses called Bath cheeses and Yorkshire cheeses, which are sold as soon as made, and if kept too long become soft and putrid. Stilton and Gruyère cheeses are intermediate; Parmesan, Dutch, Cheshire, Gloucestershire, and similar cheeses are intended for longer keeping. The poorer the cheese is the longer it will keep; and all cheese that is well cleared from whey and sufficiently salted will keep for years. The Gruyère and Parmesan cheeses differ only in the nature of the milk, and in the degree of heat given to the curd in different parts of the process. Gruyère cheese is entirely made from new milk, and Parmesan from skimmed milk. In the first nothing is added to give flavour; in the latter saffron gives both colour and flavour: the process in both is exactly similar.

In making cheese the milk is heated to about blood-heat (95° to 100° Fahr.), and the solution of rennet is well mixed with it. The coagulum, or curd, having been formed, which may be in about half an hour, it is cut into slices, the heat raised to about 135°, and after remaining about an hour at that temperature, and being stirred with a staff, the curd is found to be broken into small pieces. It is then collected on a cloth woven with wide interstices, or a sieve, to allow the whey to drain from it. When sufficiently drained, the curd is put into a wide hoop, shallow barrel, box, or something of the kind, and subjected to the action of the cheese-press. Sometimes the curd is mixed with salt, and sometimes salt is rubbed on the cheese after it is made.

In Cheshire the making of cheese is carried on in great perfection, and the greatest pains are taken to extract every particle of whey. For this purpose, the curd is repeatedly broken and mixed, the cheeses are much pressed, and placed in wooden boxes which have holes bored into them. Through these holes sharp skewers are stuck into the cheese in every direction, so that no particle of whey can remain in the curd. The elastic matter formed also escapes through these channels, and the whole cheese is a solid mass without holes, which in this cheese would be looked upon as a great defect. The salt is intimately mixed with the curd, and not merely rubbed on the outside. This checks internal fermentation and prevents the formation of elastic matter.

Gloucester and Somersetshire cheeses are similarly made—with this difference, that the curd is not so often broken or the cheese skewered, and a portion of the cream is generally abstracted to make butter.

Stilton cheese is made by adding the cream



KNIGHT'S CYCLOPÆDIA OF THE INDUSTRY OF ALL NATIONS.

15.

of the preceding evening's milk to the morning's milking. It is generally preferred when a green mould appears in its texture. To accelerate this, pieces of a mouldy cheese are sometimes inserted into holes made for the purpose by the scoop called a *taster*, and wine or ale is poured over for the same purpose; but the best cheeses do not require this, and are in perfection when the inside becomes soft like butter, without any appearance of mouldiness.

Cheeses are frequently coloured, a practice which probably arose from the notion of making the cheese look richer; but now it deceives no one. Yet, if some cheeses were not coloured they would not be so marketable, owing to the association which subsists between the colour and the quality of the cheese. The substance used for colouring is most commonly *arnotto*, which is ground fine on a stone, and mixed with the milk at the time the rennet is put in. The juice of the orange carrot and marygold-flowers are also used for this purpose; this last gives a more natural tint than the arnotto, which is too red. Cheddar, Stilton, Derby, and some other cheeses are never coloured; Cheshire slightly; but Gloucester and North Wiltshire deeply. Foreign cheeses are only coloured very slightly, if at all. Dutch cheeses are made in a very similar manner to the Gloucester cheeses, but the milk is generally curdled by means of muriatic acid. Before the curd is made up into the round shape in which it is usually sold, it is well soaked in a strong solution of common salt in water; this diffuses the salt throughout the whole mass, and effectually checks fermentation. When the cheeses are finally pressed, all the whey which may remain is washed out with the brine; salt is likewise rubbed over the outside, and they are set to dry on shelves in a cool place. The flavour of the cheese is perhaps impaired by the stoppage of the fermentation; but it never heaves, and it acquires the valuable quality of keeping well even in warm climates. The little cheeses made from cream, and folded in paper, and called Neufchâtel cheeses, are imported from France as a delicacy. They can be easily imitated, being nothing more than cream thickened by heat, and pressed in a small mould. They undergo a rapid change, first becoming sour and then mellow, in which state they must be eaten.

When a cheese which has been much salted and kept very dry is washed several times in soft water, and then laid in a cloth moistened with wine or vinegar, it gradually loses its saltness, and from being hard and dry becomes soft and mellow, provided it be a rich cheese. This simple method of improving cheese is worth knowing. A dry Stilton cheese may thus be much improved.

No less than 379,648 cwts. of foreign cheese were imported in 1849. The quantity of English cheese exported is extremely small, so much does the consumption in England exceed the manufacture.

CHEMISTRY. Under this heading, as under BOTANY and many others relating to large bodies of scientific knowledge, no systematic details can be given in this work; but the practical application of chemical principles to manufactures is illustrated in an immense range of industrial art. ALUM, BLEACHING, DYEING, COTTON PRINTING, and other articles, furnish evidence of this important application, and show how it arises that the manufacturer is so intimately dependent on the scientific chemist. Nothing that the Fourcroys, the Berthollets, the Davys, tho Faradays, the Liebigs discover, but may one day be of value to the manufacturer. The connection of science with practical application is in no case more striking or more instructive.

CHERBOURG. This important French sea-port and naval station is distinguished for its great engineering works. The naval harbour is cut out of the solid rock; it has a depth of 52 feet at high water, and is large enough to contain fifteen vessels of the line. To the south of the harbour are dry docks, and round these four slips for building the largest ships, two slips for frigates, forges, furnaces, workshops, a large timber shed, and various other establishments necessary to a naval arsenal. To protect the roadstead from winds, as well as to defend that part of it which is beyond the range of the guns of the forts, a breakwater (*digue*) was commenced about two miles north of the town, in 1784, and after many failures, disasters, interruptions, and an enormous expense, this gigantic undertaking is now all but accomplished. It extends between Isle Pélée on the east and Querqueville on the west for a length of 2 miles 593 yards, leaving an opening of 1,093 yards at the eastern end, and of 1 mile 830 yards on the west. Its width at the base is 99 yards, on the summit 33 yards; and the depth of water about it varies from 36 feet to 45 feet. In the central fort of the breakwater there is a lighthouse 65 feet high.

Cherbourg is also a place of considerable commercial activity. The principal industrial articles are cotton-yarn; hosiery; refined sugar to the amount of 12,000 cwts. a year; soda, of which 12,000 tons are produced annually in the neighbourhood; chemical products, and leather.

CHERRY. The cherry-tree includes many varieties. Of the *Wild Cherry*, the wood is remarkable for the large size of its medullary processes, which give its longitudinal section a bright satiny lustre, and render it well suited for ornamental cabinet work. The *Common Cherry* is found wild in the woods of Asia Minor, where it attains a very large size; from the time of the Romans it has ever since formed one of the most esteemed varieties of dessert fruit. The *Black American Cherry* is rather a handsome tree, of which the fruit is as large as a moderately-sized cherry. The *Choke Cherry* is a large tree growing in the United States, from 80 to 100 feet high; its fruit is not very edible in a recent state, but when dried and bruised it forms an esteemed addition to pemmican. The timber is among the best in the United States for cabinet makers' work. The *Broad-leaved Laurel Cherry* is remarkable for the abundance of hydrocyanic acid secreted in its leaves.

CHESHIRE. The most important mineral productions of this county are fossil or rock-salt, and coal. The rock-salt is obtained near the banks of the Weaver and its tributary streams. It was first discovered near Northwich, in 1670, in searching for coal; it has since been found very abundantly in the townships of Witton, Wincham, Winnington, and Marston, near Northwich. There are salt-works also at Nantwich, Middlewich, and Winsford. The salt is of two kinds, the one white and transparent, the other of a reddish brown. The former has been found by analysis to be an almost pure muriate of soda: the latter contains a small portion of oxide of iron, from which its colour is derived.

The principal salt-works are in the neighbourhood of Northwich, where there are mines in addition to brine springs. The rock-salt is found from 28 to 48 yards beneath the surface of the earth. The first stratum is from 15 to 25 yards in thickness, extremely solid and hard, and resembling brown sugar-candy. Many tons at a time are loosened by blasting with gunpowder. The second stratum is of hard stone, from 25 to 35 yards in thickness. The salt lies beneath the stratum in a bed above 40 yards thick, generally quite white and clear as crystal. The external surface above these strata is of whitish clay and gypsum. The quantity of salt annually taken from the pits around Northwich, amounts to many thousand tons; besides this quantity of fossil salt, many thousand tons are annually manufactured at the same place from brine-springs, which are from 20 to 40 yards in depth.

Coal of a good quality is found abundantly in the north-east part of the county, especially in the townships of Worth and Poynton, where there are very extensive collieries, which supply the manufactories of Stockport. At Denwell, in the hundred of Wirral, there is also coal. Copper and lead are found at Alderley Edge and the Peckforton Hills; the former place supplies a considerable quantity of cobalt. There are several quarries of excellent freestone in this county, of which those at Runcorn, Manley, and Great Bebington, are the most important. Limestone is found only at Newbold Astbury. Mowcop Hill, or Molecop, which is partly in Staffordshire, has long been famous for its mill stones. Marl is found in almost every part of the county, and is generally used for manure.

Cheshire is famous for its dairy husbandry. Dairy farms require considerable buildings; and some have been erected by wealthy proprietors in the best and most substantial manner. Although butter is made in considerable quantity, cheese is the main produce of these dairies. The making of Cheshire cheese is described in another article [CHEESE.]

Excepting at Stockport, and at other towns which share in the cotton manufacture of the neighbouring county of Lancashire, Cheshire can hardly be termed a manufacturing county. Ship-building, rope-making, sail-making, shot-making, and fringe-making, are, to some extent, carried on at Chester, where there are also tanneries, chemical works, soap works, and quarries.

CHESNUT, or CHESTNUT. This tree is available for a great variety of uses in the arts and domestic economy. There are two kinds—the *Sweet Chesnut* and the *Horse Chesnut*.

The *Sweet Chesnut* is in most cases cultivated more for its fruit than for any other purpose. In England the chesnut is eaten in many ways—raw, roasted, stewed with cream, made into soup either with milk or gravy, stewed with salt-fish, or used as a stuffing for fowls and turkey. Evelyn speaks of the chesnut as being 'a lusty and masculine food for rustics at all times, and of better nourishment for husbandmen than kale or rusty bacon; yea, or beans to boot.' In the south of France and the north of Italy, chesnuts serve in a great measure as a substitute for bread and potatoes. The nuts laid by for winter vegetable are those which fall off the trees; while those which are beaten off are carried to Paris and other large towns for immediate use. As a means of depriving the nuts of their husks, they are trodden under foot by men wearing *sabots* or wooden shoes. Chesnuts are dried in France, and preserved for many years; they are dried by the air, by the sun's heat, by a kiln, or by partial boiling, according to the mode in which they are to be used. The French make many dishes from chesnuts. *Galette* is a thick flat cake made with chesnut-meal, milk, salt, and sometimes a little butter and eggs, and baked on a hot stone or iron plate; *polenta* is a thick porridge made by boiling the chesnut-meal in water or milk, and stirring it till it forms a thick paste, something like the oatmeal parritch of the Scotch; *chatigna* is made by boiling the nuts whole, without their skins, in water with a little salt, till they become soft, and then mixing them up like mashed potatoes; *marrow-glace* is made by dipping the nuts into clarified sugar, and then drying them. The nuts are also frequently cooked by boiling them in water containing the leaves of celery or sage.

The timber of the sweet or Spanish chesnut is much used for posts, fences, stakes, hoops, &c. The wood is more fitted for such purposes than for beams or planks, as it is liable to become rent with fissures. It is used in France for making wine-casks; and for many purposes where most other woods would decay, chesnut timber is found very desirable.

In respect to the *Horse-Chesnut*, the fruit is eaten by animals; the meal is used in some places to whiten flaxen cloth, in others to strengthen bookbinders' paste; and in France attempts have been made to produce sugar and spirit from it. The timber is used for flooring, cart-linings, sabots, packing-cases, and water-pipes; on being burned it yields good charcoal and potash. The bark is used in tanning, in dyeing, and as a drug.

There were 63,033 bushels of Spanish chesnuts (as the fruit of the sweet chesnut is called) imported in 1848.

CHICORY is a perennial plant, the whole of which is bitter and aromatic; the leaves, as well as the root, have been used in medicine, in the form of a decoction, as a tonic bitter, and diuretic. It is frequently used as a salad, especially when blanched. The luxuriant growth of the leaves of the chicory, and their speedy reproduction after they have been cut, suggested the more extensive cultivation of this plant as food for cattle and sheep. But, notwithstanding its abundant produce, it has not been found so much superior to other green food as to make its cultivation general.

Chicory is now chiefly cultivated in Belgium and Germany, for the purpose of preparing from the root a powder which can be substituted for coffee. The roots, when taken up in September, are cleaned by scraping and washing, split where they are thickest, and cut across in pieces about two or three inches long. These pieces are dried by means of a slow oven or a kiln. In this state it is sold to the merchants, packed in bags. It is afterwards cut or chopped into small pieces, and roasted exactly as coffee, ground in a mill, and packed in papers in pounds and half-pounds for retail sale.

Chicory was brought into use long before the once-celebrated *Roasted Corn* of Henry Hunt. This latter was simply roasted rye; and, although used in large quantity, and sweetened with much sugar, it had but a flat and insipid taste. Chicory bears a much closer resemblance to coffee of middling quality. It was about the year 1808 that chicory became generally known in England, when Napoleon's anti-commercial policy led the nations of Europe to look around them for various substitutes for articles no longer obtainable with the same ease as before. The Germans and the French used chicory before the English; and the Germans still use it largely, often without any admixture with coffee. They even, as a question of economy, use the leaves of the plant in the same way.

There has been much said and written lately about the admixture of chicory with coffee. Many persons prefer coffee which has a little chicory added to it, as it is said that body, colour, and a soft pleasant aroma are imparted thereby. From one to two ounces to a pound of coffee is stated to be a proper proportion. It is however known that this proportion is enormously increased; for as chicory is much cheaper than coffee, fraudulent dealers do not fail to avail themselves of the circumstance. It is known that the very low-priced coffee of such vendors sometimes contains as much as two-thirds chicory to one-third pure coffee. If purchasers bought their coffee *whole*, and ground it at home, they might at once defeat this fraud.

Chicory imported from Germany pays a small import duty, and English farmers have therefore begun to grow it. Hence has arisen alarm in two quarters—the Chancellor of the Exchequer fears for his customs revenue, and the Colonial coffee-growers fear a competition against their produce. It is said that 12,000,000 lbs. of chicory are now used annually in England.

CHILE is famous for its herds of cattle. Single proprietors sometimes possess from 10,000 to 20,000 head of cattle. Live stock, jerked beef, tallow, and hides are large articles of export. Cheese is made on the banks of the Rio Maule, and sent to Peru; and butter is made in the neighbourhood of the larger towns.

Gold dust is found in the sand of nearly all the rivers which come down from the Andes, as in the Rio de Aconcagua, Rio Maule and Biobio. Silver is still more abundant, but the ore is not very rich. In 1832 however very rich silver mines were discovered, about sixty miles south of the town of Copiapò. The copper mines are very numerous, especially in the northern districts. Ores of lead, tin, and iron, are said to exist, but they are not worked. There are considerable stores of coal, but it is of bad quality. A little salt is met with, but not sufficient for the demand.

The British exports to Chile amounted in value to about a million sterling in 1849.

CHIMES. These are bells tuned to the modern musical scale, and struck by hammers acted on by a pinned cylinder or barrel, which revolves by means of clock-work. Chimes differ from *Carillons* (as the last word is commonly understood in England), inasmuch as the bells of the former are acted on by clock-work, those of the latter by keys struck by the hand. But the French apply the term *carillon* to the tune played, and, generally, to the series of bells, whether sounded by machinery or by hand, though the most accurate writers distinguish the latter kind as *le carillon à clavier*. The *carillons à clavier* comprise three octaves of bells, sounded by means of keys, similar to the pedals of an organ, which the performer strikes forcibly with hands clenched and sideways, the little fingers being guarded by a thick covering of leather. These keyed carillons are found in many towns of Holland and the Netherlands.

In Mr. Payne's musical chime clocks, for which a patent was taken out a year or two ago, the sounds are emitted by steel springs instead of bells, and elicited by pins instead of hammers. In the general arrangement of hammers and bells, the mechanism is complex and takes up much room; and it was to lessen these inconveniences that Mr. Payne introduced his new arrangement. The principle of action is almost precisely that of the musical snuff-box. Steel springs emit sounds not only equal but superior to those of bells.

CHIMNEY. In modern English houses chimney-flues are often formed within the substance of the party-wall, leaving the width and projection of the jambs entirely to the taste of the architect; and, where two adjoining houses are built with the fire-places back to back, two sets of flues are introduced in the same party-wall. Where this is not done, the flues are carried up in the projecting jambs, which are necessarily made large. In some of the best houses all the flues are so constructed as to be swept from openings in the basement story, without entering the rooms into which the fire-places open.

The chimneys, flues, or *stalks*, (as they are often termed) of our great chemical works, are among the most remarkable examples of construction. The gaseous exhalations from such works are so noxious, that an attempt is made to discharge them into the atmosphere at as great a height as possible; and a great height also increases the *draught* of the furnaces below. Hence the enormous chimneys which have been constructed within the last few years. Cotton factories have also occasionally chimneys of enormous height. At Messrs. Dewhirst's factory, at Manchester, a chimney has lately been built 243 feet high; it has a circular shaft, resting on a rectangular base 21 feet square by 45 feet high; and is wholly built of stone, of which it contains 1,700 tons. The chimney to Messrs. Dixon's cotton factory, at Carlisle, is 305 feet high; and it is octangular, and built of brick with stone angles. The chimney to Messrs. Muspratt's chemical works at Newton is 397 feet high. At Messrs. Blinkhorn's chemical works near Little Bolton is a chimney 368 feet high; it consumed in its construction 800,000 bricks and 120 tons of stone. The chimney at the great St. Rollox chemical works, near Glasgow, is 430 feet high, 50 feet in diameter at the foundation, 40 feet at the level of the ground, and 14 feet at the top. It has an inner chimney, disconnected from the outer, 260 feet in height by 16 feet in diameter. This fine chimney, being on a hill, forms a fine object for many miles; but it has needed repairs of a very troublesome and difficult kind. A great chimney was finished at Wigan in 1847, after four years of construction, in connexion with an extensive chemical work. It exceeded 400 feet in height. Almost immediately after its completion, an indentation was observed near the top, and an eminent engineer of Manchester recommended the removal of a portion of the top. About 80 feet was thus gradually removed; but the base continued to sink and displace during this period, until at length the whole ponderous structure fell in one mass, and stretched its huge mass across the Leeds and Liverpool Canal.

The chimney belonging to Messrs. Cubitt's building establishment at Pimlico, is a remarkable one. An attempt has been here made to give architectural character to that which is too often unsightly. The chimney shaft is entirely enclosed within a square tower, which presents much the appearance of an Italian campanile. The shaft is circular, 120 feet high, 5 feet internal diameter, and varying in thickness from 14 to 6 inches. The square tower envelopes the shaft without touching it. The upper portion of the tower, besides a belfry and a clock-room, affords space for a capacious cistern, useful in many exigencies. These advantages, and a saving of fuel from the shaft being kept shielded from the external cool air, are considered to pay an ample return for the increased outlay, independently of the architectural ornament thus produced.

The chimneys or flues connected with some of our mines are more remarkable than any yet described. At the great *Cwm Avon* mining and smelting works in South Wales, a chimney has been built at the top of a mountain; and flues are carried up the sides of this mountain from the works below to the chimney above. At the Tamer lead mine, on the confines of Cornwall and Devon, a steam engine has lately been set to work at a depth of 800 feet below the level of the river Tamer; and in order to give an outlet for the smoke of this engine, flues extend from it, in horizontal galleries and vertical shafts, like a flight of steps, until they reach the surface on the opposite side of the river. This united flue is nearly two miles in length.

CHIMNEY PIECE. As soon as some degree of architectural refinement began to be introduced into the habitations of noblemen, external dressings, constituting a chimney-piece, were added to the fire-place. Some of these, in which the Gothic style was employed, are marked by a fitness and propriety of character, and a happy union of simplicity with richness. Some examples—one from Tattershall Castle, Lincolnshire, and two from Windsor Castle—are given in Pugin's 'Gothic Specimens,' all of which, in regard to compactness and simplicity of composition, accord mnch more nearly with modern taste, and have a much less 'Gothic' air than the cumbrous and extravagantly ornamented chimney-pieces in the Renaissance style of the Continent, and our own Elizabethan. In these the design was carried quite up to the ceiling, so as to form a sort of architectural frontispiece, composed of two or more stages piled upon each other, and adorned with columns, pilasters, caryatides, termini, niches, &c., presenting an overloaded mass of carving and sculpture. But, though such compositions were generally exceedingly capricious, and equally fantastic and coarse in detail, some were real works of art—truly admirable for artistic beauty of design and masterly execution; such as were in the palace of Fontainebleau; two noted ones in the Hôtel de Ville at Courtrai; and one of matchless beauty for its exquisite carvings in chestnut wood, in the Palais du Franc de Bruges. In our own country, chimney-pieces of the time of Elizabeth and James I. are by no means uncommon: many are remaining, not only in mansions of that period which are still kept up, but in houses which have been almost completely modernized in all other respects.

As the more regular Italian style gained ground, the fashion of chimney pieces greatly changed. The chimney-piece and fire-place were reduced to nearly their modern proportions and dimensions, whereas the opening or fire-place had previously been of such size that a person might stand within it. Marble is now the usual material for chimney-pieces even in ordinary houses.

CHINA. Whatever may be the actual antiquity of the Chinese people, no doubt seems now to exist of their having been the authors of what are justly considered in Europe as three of the most important inventions or discoveries of modern times: the art of block-printing, the composition of gunpowder, and the magnetic compass. To these may be added two very remarkable manufactures, of which they were unquestionably the first inventors, those of silk and of porcelain. It is curious to contrast inventions of such high utility and importance with the very small progress which the Chinese have made in the sciences, as astronomy, geography, and mathematics, for which they were not ashamed to be indebted to the European missionaries. With regard to the fine arts, the Chinese have not made much progress. In painting, their colours are beautiful, but their perspective is very erroneous. In music, their instruments are numerous, consisting of different species of lutes and guitars; flutes and other wind instruments; an harmonicon of wires. touched with two slender slips of bamboo: bells and pieces of sonorous metal; drums; and a sort of clarionet, which emits as nearly as possible the tones of the Scottish bagpipe.

Through the plain which constitutes the north-east part of China runs the Imperial Canal 700 miles long. Its width, depth, embankments, cuttings, flood-gates, and bridges are on a large scale. It serves partly for navigation, partly for draining, and partly for irrigation. This canal, together with the rivers, gives a very extensive system of inland navigation in China. The plain watered by the canal is perhaps the most populous country upon earth. It contained, in 1813, 177,000,000 of inhabitants. To protect this rich plain the Great Wall was erected, which incloses China on the northern boundary, and extends over mountains and rivers for about 1,400 miles. This great work was constructed about 200 years before the Christian æra, as a defence against the nomadic tribes of Tartars. The main substance of the wall is earth or rubbish, retained on each side by a thick casing of stone and brick, and terraced by a platform of square tiles. From its eastern extremity there is an extensive stockade of wooden piles, inclosing the country of Mougden. The total height of the wall is about 20 feet, on a basis of stone projecting 2 feet under the brickwork, and about the same in height. The thickness of the whole wall at the base is 25 feet, diminishing to 23 feet at the platform. The towers are 40 feet square at the base, diminishing to 30 at the top, and about 37 feet in height.

Of the produce of this remarkable empire, tea is that with which England is most interested [Tea]. Coal, lime, gold, silver, and other minerals are met with.

Of the mechanical ingenuity of the Chinese we have spoken in the *Introduction* (p. xi). There seems no reason, however, to expect that the Chinese will take part in the Industrial Exhibition of the 'barbarians' of Europe; although the European residents at Hong Kong and Canton have contributed towards the funds of the Exhibition.

The materials employed by the Chinese in house-building are wood, of which that most in use is the nan-mon, a kind of cedar: stone, marble, bricks, bamboo, and glazed or porcelain tiles are also employed. The construction of houses is directed by a public functionary, whom we may not inaptly designate a district surveyor. Every one is obliged to build his house according to his rank, and for every house a certain size and details are fixed. The ordinary habitations have one floor. The houses called heon, that is, of many floors, were once very much the fashion, and some were built about 211 feet high. Wooden columns, so placed as to support the roof, are common, and are from eight to ten diameters in height. They are fixed on stone or marble bases, but have no capitals. The roofs, which are slightly constructed of bamboo, are often double, and resemble one roof rising out of the other: they turn up at the eaves, at the angles of which are hung grotesque figures of dragons, &c. Not the least singular appearance in a Chinese house is the door, which is often a complete circle; the window frames and sashes are formed of small pannels of various forms moulded out of clay, and neatly joined together. The sills of doors are of stone. The palace of Pekin is on an immense scale, 2,513 feet by 3,235 feet. It is divided into a number of courts, is composed of towers, galleries, porticoes, halls, and immense buildings, and, as a whole, has an imposing appearance.

CHINA WARE. [Porcelain.]

CHINCHILLA. This small animal, a native of South America, is in request for the sake of its fur. That which comes from Peru is rougher than that brought from Chile, but not always so beautiful. Great numbers of these animals are caught in the neighbourhood of Coquimbo and Copiapó, generally by boys with dogs, who bring them to Santiago and Valparaiso, whence they are exported. The Peruvian skins are either brought to Buenos Ayres from the eastern parts of the Andes, or are sent to Lima. The extensive demand in Europe for this fur has occasioned a very large destruction of these animals.

CHLORINE is an elementary gaseous body discovered by Scheele, in 1774. It has a very powerful and disagreeable odour, is very suffocating, even when considerably diluted with air, and its taste is astringent. Faraday has shown that, when this gas is subjected to a pressure of about four atmospheres, and kept cool, it is condensed into a yellow limpid fluid, which is extremely volatile, and, when the pressure is removed, rapidly reassumes the gaseous form. Neither light, heat, nor electricity produces any change in the properties of chlorine gas, provided it be dry; but, if it be moist, then light causes it to decompose the water.

One of the most curious and important properties of chlorine is the power which it possesses of destroying the colour of animal and vegetable matter in general, and hence its extensive application to the purpose of bleaching. [Bleaching.] This is effected however not by dry chlorine, but when moisture is present. Chlorine is a powerful supporter of combustion: if certain metals, and especially antimony, in the state of powder, be thrown into chlorine gas, they burn spontaneously; phosphorus also exhibits similar phenomena. Chlorine is a powerful disinfectant; Sir William Burnett's 'Disinfecting Fluid' consists of chloride of zinc. Mr. F. Smith has recently (1847) introduced a small apparatus for making chlorine, to be used in hospitals, or houses, or rooms, where the air is likely to be tainted.

Many of the compounds of chlorine with other substances are highly important. The most so perhaps is *Muriatic* or *Hydro-chloric Acid*, which consists of chlorine and hydrogen; it is a colourless gas, with a pungent odour and an acrid taste; it extinguishes burning bodies, and excites coughing; it is expanded by heat, and decomposed by electricity; it readily absorbs atmospheric moisture, and then becomes liquid muriatic acid, which has the smell and acid properties of the gas.

Muriatic acid is largely used in chemistry and the arts. When it is mixed with nitric acid, it is decomposed, and a solution of chlorine is obtained, which, under the old name of *aqua regia* or modern name of nitro-muriatic acid, is used for dissolving gold and platinum.

The manufacture of chlorine at the Felling Chemical Works, near Newcastle, according to the patent obtained by Mr. Lee in 1842, is conducted as follows:—Each of the chambers for the manufacture is covered by an arch, over which the furnace flue is led, so that the heat may be transmitted downward through the arches to the materials placed within the chambers. In each chamber is a stone trough, such as is used for the condensers and flues of alkali works. One side of each chamber is furnished with a leaden door, and at the opposite side is a pipe of lead or of earthenware for the escape of the chlorine. The fire being kindled, and the chamber sufficiently heated, lumps of manganese are placed in the troughs, and the doors closed; muriatic acid is then introduced through glass tubes, conveniently placed for that purpose. The chlorine is speedily given off, and passes into another chamber; and the muriate of manganese is drawn off from tho troughs on the completion of the process by means of syphons.

CHLOROFORM is a peculiar compound limpid fluid, which is soluble in alcohol and æther, and dissolves iodine, phosphorus, and sulphur. Although mankind had for a long time had recourse to various narcotic agents for relieving pain in disease, it was not till the discovery by Drs. Jackson and Norton, in America, of the narcotising powers of the vapour of æther, that such agents were employed for the purpose of relieving the dreadful suffering endured in surgical operations. This discovery can only be regarded as second in importance to that of vaccination, as a preventive of small-pox, by Dr. Jenner. Scarcely had it been generally known that æther possessed the power we have mentioned than, in the latter end of the year 1847, Dr. Simpson, of Edinburgh, discovered that the vapour of chloroform possesses the same powers. The discovery that the vapour of chloroform produced the same effect as that of æther produced scarcely less sensation than the discovery of the powers of æther itself. For it possesses many advantages over æther in its application to the production of insensibility. These are—1. A smaller quantity of chloroform than of æther is required to produce the same effect; for thirty or forty drops upon a handkerchief or sponge, and applied to the nostrils, are sufficient to produce the desired effect. 2. The action of chloroform is more rapid and complete, and more persistent than that of æther. 3. Frequently after taking the vapour of æther, sickness and headache come on; but, although these effects sometimes take place with chloroform, they are not so frequent. 4. The expense of chloroform is much less than that of æther, from the small quantity required.

Chloroform is obtained by distilling a mixture of chloride of lime, water, and spirit.

CHOCOLATE. [COCOA.]

CHORLEY is one of the busy cotton-manufacturing towns of Lancashire. The chief articles of manufacture are calicoes, muslins, and ginghams. Eight cotton factories, two print works, two weaving sheds, bleaching works, a paper-mill, coal-mines, and stone-quarries, afford employment to many of the inhabitants. Another large cotton factory has been just completed. A new patent brick and draining-tile manufactory has been recently established. Four miles from Chorley, lead and carbonate of barytes are found. The Leeds and Liverpool canal, and the Lancashire and Yorkshire Railway, are of great benefit to Chorley in affording facilities for the carriage of goods. A very large increase has taken place in the population and prosperity of the town owing to the great increase of calico-printing.

CHROMATYPE is the name given by Mr. Robert Hunt to a variety of the photographic process discovered by him in 1842. It derives its name from some of the chromates, especially the chromates of mercury and copper, employed in preparing the photographic paper.

CHROMATIC THERMOMETER is the name given by Sir David Brewster to an instrument consisting of several rectangular plates of glass placed with their surfaces in contact, and intended to measure the difference between the temperature of the glass and of any body, solid or fluid, which may be applied to it. The temperature induced in the glass must however be below that at which the glass would become red hot. The heated body, solid or fluid, being in contact with the edges of the glass plates, the inequality of action caused by differences of temperature in the parts of each plate of glass gives rise to differences of tint in the polarized light of the glass, which differences are made to measure (scientifically though not practically) differences of temperature.

CHROMIUM, a metal discovered by Vauquelin in the year 1797, is pulverulent, of a yellowish white colour, and metallic lustre. It suffers but little change by exposure to the air, and acids act upon it but slightly. Chromium combines with many of the elementary substances. One of the oxides of chromium has a green colour, and is the colouring matter of the emerald; it is employed to give a green colour to glass and porcelain. The chromate of lead and other compounds of the metal are of great value in the arts.

CHRONOMETER. Such time-keepers as are used for determining the longitude at sea, or for other purposes where great accuracy is required, combined with portability, are called by this name. Some are made for the pocket, resemble ordinary watches in appearance, and, like them, are made to go thirty hours with once winding up. Marine chronometers are usually larger, with dial-plates three or four inches in diameter, and made to go from two to eight, or, by some recent improvements, even as many as thirty-two days with once winding up. They indicate hours (from I. to XXIV., to avoid the possibility of an error of twelve hours), minutes, and seconds, often on separate circles; and they are furnished with a small hand to indicate the days which have elapsed since the winding up. The mechanism is enclosed in a brass box, mounted on gimbals, so as to preserve one uniform position, and inclosed in a mahogany case.

The greater part of the mechanism of a chronometer resembles that of a common watch, but is constructed with every possible provision to ensure accuracy. They differ from the common watch chiefly in the *detached escapement* and the *compensation balance.* The former is a contrivance by which the balance, the vibrations of which constitute the actual measure of time, is, during the greater part of its movement, entirely detached from, and consequently unaffected by, the train of wheel-work from which its impulse is derived; the wheels, in fact, standing still through the greater part of each vibration. The *compensation-balance* is a beautiful contrivance for counteracting the effect of changes of temperature, which, by causing an ordinary balance to expand and contract, occasion a variation in the extent of its vibration, and consequently in the rate of going of the time-piece of which it forms the essential feature. This correction, in the ordinary compensation-balance, is effected by forming the rim of the balance of two semicircular slips of metal, fixed at one end only, and each consisting of a very narrow riband of steel joined to an outer rim of brass. Each of these semicircular slips, consisting thus of two metals differently affected by heat, is capable of altering its shape with every change in the temperature to which the chronometer is exposed, in such a way as to keep the vibrations of the balance always the same. In the first marine chronometers, constructed by Harrison, this object was attained by applying such a compensating apparatus to the balance-spring. Arnold, following, probably unconsciously, in the track of the great French watch-maker, Le Roy, applied it to the balance itself. Many other improvements have been made in the chronometer, rendering it almost as perfect as any thing from the hand of man can be expected to be; and of late years very ingenious contrivances have been devised by Messrs. Dent, Eiffe, and Molyneux, for correcting certain irregularities of action in the ordinary compensation-balance and producing a balance surpassing it in accuracy of movement as it surpasses the balance of a common watch.

The wonderful accuracy of modern chronometers was made the means in 1839 of determining the longitude of New York, as compared with Greenwich. The first experiment was made on the occasion of the first trip across the Atlantic by the *British Queen.* The longitude determined by that mode differed 2·63 seconds from that determined by the usual astronomical means. Mr. Dent was dissatisfied with a discrepancy—marvellously small to the minds of others—but large in the estimation of one accustomed to the performances of chronometers; and he determined to made a second attempt. He placed four chronometers under the care of Captain Roberts, the rates of which had been previously ascertained. The chronometers made a voyage out and home in the *British Queen,* showing, of course, *Greenwich time* all the while; and on being compared in America with other chronometers which marked *New York time,* the difference of longitude was measured by this difference of chronometer time. So astounding was the accuracy of those instruments, that while the difference of longitude between the observatory at Greenwich and the City Hall at New York is found by the best astronomical methods to be 4 h. 56 m. 0·72 s., it was measured by the chronometers to be 4 h. 56 m. 0·24 s.,—a difference of less than half a second! It was found that the chronometers were able to withstand the shaking of the vessel, and all other disturbances incidental to a steam-ship, without perceptibly marring their action.

Mr. Dent, shortly afterwards, determined by chronometric means the difference of longitude between Greenwich and Devonport. As ascertained by the Trigonometrical Survey, the difference of longitude, between the Observatory at Greenwich and the flag-staff on Mount Wise, near Devonport, is 16 m. 38·1 s.; while the difference given by a mean of four chronometers was 16 m. 39·8 s.—a difference of less than two seconds.

During the last five years, there have been 219 Admiralty chronometers at Greenwich Observatory. It is curious that in these successive years, 1845-6-7-8-9, five different makers stood successively first on the list, in respect to the accuracy of the chronometers made by them; showing how closely the spirit of honourable scientific competition has brought them on a level one with another. Of the whole number 79 were purchased for the public use; the highest price paid was 68*l.* 5*s.* [CLOCK AND WATCH MAKING.]

CHURCH. The principal type of a complete church, as an architectural structure, is a cathedral. Almost every cathedral is varied in plan, although the leading features, the nave and choir, are found in almost all. The plan usually consists of a galilee, or chapel, at the principal entrance; the nave, or main body of the church; the side aisles, which do not rise so high as the nave, and are placed on each side of the nave, sometimes with chapels, at other times without, between the openings formed by the windows; the choir, or place for the ceremonies of the church; the transept, or division at right angles to the end of the nave next the choir, which projects on each side, and forms a cross on the plan. Some cathedrals have a double transept, and the transepts have often aisles. At the end of the choir is the high altar, behind which is occasionally a lady chapel, or chapel to the Virgin. The choir end of a cathedral is sometimes terminated by an apsis or semicircular end. Along the sides of the choir are ranged richly carved seats, ornamented with arches, pinnacles, and tracery, carved in oak. The bishop's seat, richer than the others and raised above them, is on one side, at the eastern end. The choir has also side aisles. Cloisters and a chapter-house are usually attached to English cathedrals. The minor parts of a cathedral are the muniment room, the library, the consistory court, the vestries of the dean and chapter, minstrels' chapels, a font, and a minstrels' gallery. Beneath the body of the cathedral there is usually a crypt, or low basement, supported on arches springing from thick columns, as in Canterbury Cathedral and others. At the point of intersection of the transept with the nave there is usually a tower, sometimes surmounted by a spire. The nave of a Gothic cathedral is supported by clustered columns, arched from one to the other, over which there is usually a row of small arches forming a gallery, which is called the triforium, and above are windows called clere-story windows. The chapter-house and cloister are large and important features in many of our cathedrals. The finest chapter-houses in England are of a polygonal form, and have in some cases a column, or cluster of columns, in the centre, to support the vaulted roof. The cloistures are rectangular inclosures, with a richly ornamented and arched gallery running round the sides. Such are the leading features of the cathedrals and large churches of Europe. The numerous cathedrals of France, Italy, and Germany present beautiful specimens of architecture, not only in the Gothic style, but also in the Italian style. St. Peter's at Rome is the largest cathedral in Europe. Vienna and Strasburg have the highest spires; the former is 465 feet, the latter 456 feet high.

CHURN. The common churn for making butter is a wooden cask rather wider at bottom than at top, covered with a round lid having a hole in the centre. Through this hole passes a round stick about four feet long, inserted in the centre of a round flat board having holes in it; the diameter of this board is a little less than that of the top of the churn. The milk is churned by giving a vertical movement to the board immersed in it.

There is obviously a great waste of power in such a contrivance; and many forms have been devised to render the work of the churner more efficacious. One of the most recent is the *atmospheric churn*, made by Mr. Samuelson. It consists of a square box, inside which are four vanes or boards, made to rotate round a central horizontal axis, the handle of which projects through one side of the box. Two of the vanes are perforated, and two are solid; the former break the cream and separate the butter from the butter-milk; while the latter cause air to be forced into the milk. These churns are made of various sizes, to churn from 4 to 96 quarts, and are sold from 25*s.* to to 115*s.* each.

CIDER, or CYDER. There are two cider districts in this country. The Hereford cider district is comprised in the four counties of Hereford, Gloucester, Worcester, and Monmouth; the Devonshire cider district in those of Devon, Dorset, Somerset, and Cornwall.

The principal kinds of apple used in these districts for cider are the New Foxwhelp, the Wilding, the Cherry Pearmain, and the Yellow and Red Norman. In the Devonshire district, the situations chosen for orchards are generally hollow dells or shelving banks, in the neighbourhood of the farm-houses, the land on which they are planted being put to little other use; while in the Hereford district the choice is determined chiefly by the quality of the soil, without reference to the position of the farm-house. Very little attention is paid to enriching the soil round the trees when once they have been planted. In by far the largest proportion of orchards, with the exception of gathering the fruit, nothing is done to the trees from the beginning of the year to the end. The fruit of the different varieties of apple ripen at different times of the year, earlier or later, according to the season. The customary method of picking the fruit is by striking the trees with poles, provincially called 'poulting,' and then gathering the fallen apples; but it is better economy to pay a small extra price for collecting the fruit which falls at several times. When the apples have been gathered, each sort by itself is collected into heaps, about ten inches deep, where they remain for a month, or more, until they become mellow; they are then ready for the mill.

Cider is manufactured with very rude machinery, by the following process :—The apples are thrown into a circular stone trough, usually about eighteen feet in diameter, called the *chase*, round which the *runner*, a heavy circular stone, is turned by one or two horses. The crushed pulp or *must* is pressed between horse-hair cloths, and the juice expelled. This juice is poured into casks, placed either out of doors, or in sheds where there is a free current of air. In about three or four days the liquor ferments; the thick heavier parts subside as a sediment at the bottom of the cask, and the lighter becomes bright clear cider. This is then *racked*, or drawn off into another cask.

The fermentation of cider is a process requiring great care and skill. *Slight* fermentation will leave the liquor thick and unpalatable; *rapid* fermentation will impair both its strength and durability; *excessive* fermentation will make it sour, harsh, and thin. It is not the habit of the farmer to add sugar, treacle, brandy, or any colouring matter to the liquor; it is only adulterated in the hands of cider dealers and publicans, who often 'doctor' up sour cider to make it palatable.

At the beginning of January the cider is moved into cellars, where by large growers it is frequently stored in casks of great capacity, containing 1000, 1500, or even 2000 gallons. In March the liquor is bunged down; it is then fit for sale, and may be used soon afterwards, though it will greatly improve by keeping.

Cider of good quality is made in Ireland, in the counties of Waterford and Cork; in Normandy, whence we have many of our best apples; in Belgium; and of inferior quality in Germany. It is also made in abundance, and of excellent quality, in many parts of the United States of North America.

CIGAR. The manufacture of cigars is exceedingly simple. A boy, with a quantity of unstripped leaves before him, takes them one by one, strips them, and then passes them to the cigar-maker, who is seated in front of a low work-bench, which has raised ledges on every side excepting that nearest to him. He takes a leaf of tobacco, spreads it smoothly before him on the bench, and cuts it to a form resembling one of the gores or stripes of a balloon. He then lays a few fragments of tobacco leaf in its centre, and rolls the whole up into a form nearly resembling that of a cigar. The next operation is to place the partially-formed cigar in an iron guage, which cuts it to a given length. The maker then lays a narrow strip of leaf upon the bench, and rolls the cigar spirally in it. All this is done with great rapidity, a few seconds being sufficient for the production of a cigar. The cigars are finally dried for sale.

The following account of the cigar manufacture at Havannah appeared in some of the London journals in 1841:—The greatest manufacturers of Havannah cigars are Cabanas, Hernandez, Silva, and Rencareiul; there are a hundred others of less note, who make from 10,000 to 100,000 a day. The cigar is composed of two distinct parts, the inside and the cover. For these, two different kinds of leaves are used; of which that for the cover is generally finer in texture and more pliant. These leaves are damped the night previous to their being made up; when rolled, they are placed on a large table, where they are divided into the various qualities of first, second, third, &c., and priced accordingly. Those which are most carefully rolled are called *Regalias*, and are sold at 22 to 26 dollars per thousand; while the second best, which are of the very same tobacco, and made by the same man, only with less care, are sold at 14 dollars; and others are done so low as 6 dollars. D. Hernandez employs about fifty men in his manufactory. Of the best common cigars, a workman can make a thousand a day; of the Regalias six hundred. The daily issues from that immense *fabrica* are about 30,000 cigars; which at 14 dollars per thousand would give nearly 100*l*. per day. They pay an export duty of half a dollar per thousand, and an import duty in England of nine shillings. The very best in quality do not find their way to Europe, because they are not fashionable here: they are generally dark coloured; whereas a light coloured and smoothly rolled cigar is preferred to the strong and highly flavoured rough ones, which are the best.

CI'NCHONA; *Jesuits'* or *Peruvian Bark*. By whom the important properties of the various species of this genus was first made known to Europeans is unrecorded. The native Peruvians attached no febrifugal importance to the bark. Its introduction to Europe took place through the Spaniards in the year 1640. Little was known of the tree producing this substance till the voyage of La Condamine, who, in 1738, first printed a detailed account of *Quinquina*, as it was then called.

The manner of collecting the Cinchona bark of commerce is thus described:—In the month of April the preparations for an expedition commence; and in May the people start for the forest, whence the last green bales are transmitted home in November. They fell the trees close to the root, sparing those trunks which appear too young, as, till they have attained maturity, the bark is of no value. The next process is to divide the stems into pieces of uniform length, rejecting only the very smallest branches. The bark is then cut lengthwise, so as to remove the rind without injuring the wood or severing any of the fibres. In a few days the bark is taken off in strips as broad as possible. In the market the value of the bark depends on the celerity with which it is dried. In the dense forests it is impossible to perform this operation properly, and therefore the bundles of green bark are dispatched with all speed to the nearest inhabited place, where the person appointed to take charge of them is stationed. They are laid in a spot exposed to the full action of the sun, and the greatest care is requisite to protect them from the wet.

Cinchona barks, in England, are classed under three heads — pale, yellow, and red barks. Of each there are several varieties. Of the *Pale Barks*, three varieties are known in English commerce:—1, Crown or Loxa Bark; 2, Gray, Silver, or Huanuco Bark; 3, Ash Bark. These are always quilled, and never in flat pieces. The powder, which gives the name, varies from gray to fawn colour. The Crown Bark occurs in pieces from 6 to 14 inches long, the quills varying in diameter from the fourth or even smaller part of an inch to nearly half an inch. The colour of the exterior is marked dark gray, in some specimens verging to brown. The odour resembles that of tan. The taste at first is slightly astringent, and faintly acid; afterwards very astringent, somewhat bitter, but not acrid. The Gray and Ash Barks differ from the Crown chiefly in tint.

The *Yellow Barks* also present three varieties. The variety best known in England occurs in two forms—quills and flat pieces; the quills were formerly most prized, but all well-informed persons now prefer the flat pieces as much richer in quinia. The external surface is generally grayish brown, inclining to blackish, yellow, or whitish, according to the kind of lichen by which it is beset. The flat Yellow Bark, or that in splints, occurs either with the epidermis or divested of it.

The *Red Bark*, of which one kind only is known in English trade, was not much used in Europe till 1779. It occurs in quills and flat pieces, most frequently in the latter form.

The various forms of Cinchona Bark are justly considered the most valuable tonic and febrifugal medicines we possess; and the commerce in them has thereby become important.

CINCHONIA, is a vegetable alkali contained in all the varieties of Cinchona, but principally in the *Cinchona lancifolia*, or pale bark. Cinchonia has a peculiar bitter taste; and combines with many of the acids to produce a peculiar class of salts.

CINNABAR. [MERCURY.]

CINNAMON has been known to European nations from very high antiquity. That which is now chiefly consumed in England is the aromatic bark of a small tree found in the island of Ceylon. The time for stripping off the bark is from May to October. The bark, after being removed from the branches, is tied up in bundles for twenty-four hours, during which time a sort of fermentation takes place, which greatly facilitates the separation of the outer part of the bark from the cuticle and the epidermis, which is very carefully scraped off the Ceylon cinnamon. It is then rolled up into quills, or pipes, about three feet in length, the thinner or smaller quills being surrounded by larger ones, a mark which always distinguishes cinnamon from cassia. It is then conveyed to Colombo, where it is sorted by government inspectors into three kinds, of which the two finest alone are allowed to be exported to Europe, while the third, or inferior kind, is reserved to be distilled, along with the broken pieces of the other two, for the purpose of obtaining the oil of cinnamon. The select cinnamon is formed into bales of about 92½ lbs. weight, containing some pepper or coffee, and wrapped in double cloths made of hemp.

This fine cinnamon occurs in pieces about forty inches in length, generally containing from six to eight rolls or quills in each, one within the other, of the thickness of vellum paper, of a dull golden yellow colour. It is very fragrant, agreeably aromatic, taste pleasant, warm, aromatic, slightly astringent. Analysed by Vauquelin, it yielded volatile oil, tannin in large quantity, an azotised colouring matter, a peculiar acid, mucilage, and feculum.

The root of the cinnamon tree yields a kind of camphor, and the leaves yield an oil which resembles oil of cloves, which it is often used to adulterate. This is quite distinct from the oil of cinnamon obtained from the bark. The ripe berries yield by decoction a solid volatile oil, similar to the oil of junipers.

Cassia is often mistaken for cinnamon; but they differ in the following particulars: The bales in which Cassia arrives are much smaller, containing only from two to four pounds, bound together by portions of the bark of a tree. The quills are thicker, rolled once or twice only, and never contain thinner pieces within; the diameter of the bark is much thicker than that of cinnamon, and harder, and the outer rind less carefully removed. It has the odour of cinnamon, but fainter and less grateful; the taste more acridly aromatic, pungent, less sweet, at the same time more powerfully astringent, yet mucilaginous.

Oil of Cinnamon is obtained chiefly from the fragments which fall from the quills during the inspection and sorting at Colombo. These fragments are coarsely powdered, and, after being immersed for forty-eight hours in sea-water, are distilled, when a milky fluid comes over, which separates into two parts, a light oil which floats on the water, and a heavy one which sinks. In time a spontaneous separation takes place, and there are formed transparent crystals of *stearopten*, or cinnamon camphor. *Oil of Cassia* is also obtained by distillation; at first it is whiter than oil of cinnamon, afterwards it becomes yellow, but never of such a fiery yellow as cinnamon-oil. The odour is agreeable, but not so delicate; the taste, acrid, burning, but different from cinnamon.

Oil of cinnamon, as a costly article, is often adulterated with oil of cassia; with the oil of cassia-buds; with the oil of the *Cérasus lauro-cerasus*, or cherry-laurel; and it is also said with oil of bitter almonds, an exceedingly dangerous intermixture.

Cinnamon is an extremely valuable aromatic stimulant, useful both in cookery and in medicine. Cassia has similar properties in a less degree.

347,368 lbs. of cinnamon were imported in 1848.

CIPOLIN is a variety of green marble with white zones, found in the vicinities of Rome and Autun.

CIRCLE. The following rules respecting the circle are of constant application in mechanical operations. To find the circumference of a circle (with more than sufficient nearness for practical purposes) take the 113th part of 355 times the diameter, or 3.14159 times the diameter. To find the area in *square* units, multiply the number of units in the radius by itself, and take the 113th part of 355 times the result (or multiply by 3.14159).

CIRCUMFERENTOR. This instrument is a species of surveying compass, consisting of one circular plate of brass, graduated, and of another turning on the same axis, which carries a vernier; these are supported on a tripod stand, and may be rendered horizontal by means of small spirit-levels. The upper plate carries two sight-vanes or perforated plates in vertical positions, at the opposite extremities of a diameter, and through these an object is seen when the *bearing* of a station line from the magnetic meridian is to be found.

Such an instrument, being far inferior to a theodolite in respect of the accuracy with which by its means a survey may be made, is not much used in Europe; but in the United States of America, and in the British Colonies, where land is less valuable, it is almost the only instrument employed.

CITHARA was an ancient stringed instrument, supposed to have been somewhat like the modern guitar.

CITRIC ACID. This acid exists in numerous fruits, particularly those of the orange tribe, such as the lemon and lime, either alone or with malic and other acids; sugar, mucilage, and extractive are also present. It is colourless, inodorous, and extremely sour. When decomposed, it yields pyrocitric acid, and several other compounds. The citric acid is separated and purified on a large scale. Citric acid, when crystallised, has scarcely any odour, but a very distinct acid taste. It is soluble in cold and still more in warm water. It is used as a discharge in calico printing.

Citric acid combines with ammonia, potash, soda, iron, zinc, copper, silver, lead, and other bases, to form salts.

Concentrated citric acid is somewhat caustic, but lemon juice is gratefully acid. To imitate the natural state, citric acid is only given largely diluted. In this state it proves a pleasant drink in fevers and diseases where the temperature of the body rises above the natural standard. According to Broussais, it agrees better than any other acid with the stomach when affected with acute inflammation. It is not so pleasant as lemonade prepared from new fresh lemons; and, according to the statement of Sir G. Blane, the solution of citric acid is not so efficacious in the prevention and cure of sea-scurvy as the recent lemon-juice. This is attributable to the absence of the volatile oil and the bitter principle of the rind, which are valuable adjuncts to the citric acid in its action on the stomach. The utility of lemon-juice in promoting the digestion of gelatinous meats, such as veal and turtle, is well known. Fresh lemon juice may be preserved in bottles in the same way as ripe fruits, by boiling the bottles in which it is contained for half an hour, first placing them in cold water and gradually heating it, and, as soon as the contents of the bottles have fallen to the temperature of the air, closing them hermetically. Where lemon juice so preserved, or fresh lemons, cannot be obtained by ships on long voyages, the dissolved citric acid, to which a portion of an alcoholic extract of lemon peel may be added at the time of using, is sometimes used when apprehensions of scurvy are entertained.

Citric acid, as well as lemon juice, is much employed to decompose alkaline carbonates, forming therewith pleasant effervescing solutions.

CITRON, is one species of that important kind of fruit which includes the LEMON and ORANGE.

CIVET is a perfume obtained from an animal bearing the same name. The animal is a native of North Africa, and is two to three feet in length. The perfume is procured by scraping the inside of the pouch with an iron spatula, at intervals of three or four days; about a drachm may be obtained each time.

As civet sells at rather a high price, that which goes by the name in the market is too often adulterated with suet or oil.

CLACKMANNANSHIRE. This Scottish county presents a fair amount of produce and manufacturing industry. In the parish of Alloa are distilleries, breweries, manufactures of yarns, plaidings, shawls, tartans, druggets, and blankets, corn and flour mills, besides a glass work, a foundry, a brick and tile work and pottery, and a tan work. There are salmon fishings in the Forth. The manufacture of Scotch blankets and serge was formerly carried on at Tillicoultry, but shawls and tartans have been found more lucrative, and have engrossed much of the industry of this populous village. Small quarries of sandstone and limestone are wrought in various parts of the county, but the most important branch of industry pursued is the working of the extensive coal fields in Alloa and Clackmannan parishes, which form that part of the county lying on the banks of the Forth. Coal has been wrought here for 200 years, and there is an immense annual exportation of that article from Alloa. The occupation next and almost equal in importance is the iron manufacture, at Devon iron works, on the banks of the stream of that name, and in Clackmannan parish. Small railways connect these several works with Alloa harbour and Clackmannan Pow, and they will soon be brought into ready communication with all the great markets by the Stirling and Dunfermline line of railway.

CLARET, a name used in England to denote the red wine of Medoc, or, more correctly a mixture of that wine with some other more full-bodied. The word *clairet*, from which the name is derived, is used in France to signify those wines which are red or rose-coloured; but the name, as understood by us, is not known in that country. [BORDEAUX; WINE MANUFACTURE.]

CLARIFICATION, the process of rendering a fluid clear by separating the substances which, being suspended in it, render it turbid. Isinglass, gelatine, bullocks' blood, and white of eggs, are employed for the purpose. In the great London porter-breweries, a liquid solution is prepared, of which isinglass is one ingredient; and a very small portion of this 'fining-liquor' is put into every butt of beer.

CLARINET, a musical instrument made of wood, similar in shape to the oboe, but of rather larger dimensions, and having a fixed mouth-piece containing a reed, which forms the upper joint of the instrument. In the orchestra three instruments are employed, of different dimensions, namely, a C, a B, and an A clarinet, to play in different modes or keys. The compass is from E in the base to G in altissimo. The clarinet was invented about a century and a half ago, by Denner of Nürnberg. The *Base Clarinet*, and the *Contra-Base Clarinet*, invented by Streitwolf, about twenty years ago, are longer, larger, and deeper-toned instruments than the above.

CLARION, was the name of a shrill kind of trumpet, not now in use.

CLAVICHORD, was the name of a musical instrument which preceded the pianoforte. The strings were struck by brass pins, projecting from the remote ends of the keys, instead of by hammers; but the tone was one which would now be deemed intolerably harsh and wiry.

CLAY. Any natural mixture of earths which breaks down or disintegrates in water, and affords a plastic ductile mixture may be called a clay. *Pipe-Clay* is of a grayish-white colour, has an earthy fracture, and a smooth greasy feel. *Potter's Clay* disintegrates by exposure to the air; when mixed with sand it is made into bricks and tiles. *Stourbridge Clay* is of a dark colour; it is extensively employed in the manufacture of crucibles. *Brick-Clay* or loam varies much in appearance; texture, and composition; it lies in abundance upon the London clay, and frequently rests upon an interposed bed of sand. *London Clay* is a blueish deposit, often including beds of sandstone. *Plastic Clay* consists of a variable number of sand, clay, and pebble beds, irregularly alternating, lying immediately upon the chalk. *Porcelain Clay* is of various shades of white; it is dull and opaque; occurs friable or compact; feels soft to the fingers, and adheres to the tongue.

Clay is an essential component part of all fertile soils. A clay soil consists of a large proportion of alumina united to silica of various degrees of fineness, and frequently also a portion of carbonate of lime. In rich wheat soils the silica is very fine, and intimately mixed with the alumina; but English clays are not usually of this character, and are not so much approved for wheat crops as lighter soils. Clay land will bear a repetition of the same crops much oftener than lighter lands. The great disadvantage of clay soils in a moist climate like that of Great Britain arises from an excess of water, and the obvious remedy is perfect draining of the subsoil. [DRAINING.] Clay is extensively used in many parts of England to improve light land, by being carried on the surface in considerable quantities. Burnt clay is used as manure. Clay by burning alters its nature; it becomes insoluble in water, and loses its attraction for it; it then resembles silicious sand, and may greatly improve a very strong retentive clay, tempering it and rendering it more porous.

The Newcastle district will furnish many specimens of clays used in the Arts, for exhibition at the approaching industrial festival. The manufacture of fire clay into bricks, &c., is carried on very extensively in the neighbourhood of this town; and among the articles exhibited, formed of clay, will be fire-bricks, vases, pedestals, and ornaments of various kinds. Stourbridge will in like manner send specimens of those clays and clay-manufactures which have given celebrity to that town.

CLE'PSYDPA. Before the invention of pendulum clocks, it was not unusual in astronomical observations to measure time by the flowing of water, upon a principle which, in its most simple application, resembled that of the hour-glass, but which was varied by contrivances for accuracy or ornament. Such a contrivance was called a *clepsydra* or water-clock. The Chaldeans divided the day into twelve equal parts by a Clepsydra. Water-clocks were used in Egypt, Greece, and Rome; and there is evidence that they were used in India in the twelfth century. Many fanciful forms of Clepsydræ are given in old works on Hydraulics; but modern clock and watch work has rendered them quite obsolete.

CLICHÉE MEDALLIONS. Large medallions are sometimes made in France by a process called *en clichée*. The metal of which the medallion is formed is used while in a pasty state, between solid and liquid. Such medallions, unlike more elaborately wrought coins and medals, have a device on one side only, on which side alone they are intended to be seen; they appear to have been devised ir France, where large and cheap medallions are more prized, and are more extensively produced, than in England. In the time of Napoleon, it was customary to make large medallions *en clichée*, bronze them, mount them into the lids of snuff-boxes, and protect them with convex glasses.

The medallions are made in the following way. The metal employed is *fusible metal*, [ALLOY] which melts at a very low temperature. This being melted in an iron vessel, a little is taken up in a ladle, and agitated until it assumes a pasty consistency. Sufficient to form one medallion is poured on a piece of clean paper, placed in the bottom of a box enclosed on all; a stamper is made to fall suddenly on the mass, and impress a device upon it, which device remains when the metal cools. The device is produced in one of two ways. In one case the original medallion, which is to serve as a copy for those to be made, is used as a model from which a *mould* en clichéo is made, and this mould is fixed, face downwards, to the bottom of the stamper; while in the other case a die is engraved, and this die itself is fixed to the stamper. It is obvious that the same results are produced by both means. The box contains a little simple mechanism for regulating the descent of the stamper, and to prevent the semi-liquid metal from splashing about. The medallions are made one by one, and removed as fast as made.

The medallions are generally finished by bronzing. The back and edge are brought true by turning in a lathe; and the medallion is then subjected to some one of many different routines of processes, any of which will impart a bronze-like colour to the surface.

The dies or moulds for clichée medallions may be formed of iron, brass, copper, wood, sulphur, or plaster. The Italian figure casters often employ a kind of clichée method in producing moulds for small casts.

CLITHEROE, in Lancashire, was, until recently, a place of little trade; but extensive print works and cotton manufactories have been established, which, along with the lime-kilns, provide ample employment for the increasing population. The neighbourhood abounds with limestone, for which there is a great demand, as it can now be conveyed by water to any part of the kingdom. The chief establishment in the town is the celebrated print-works of Messrs. Thomson at Primrose Lodge, on the south-west margin of the town. A dam has been thrown across the valley of Mearley Brook, to form a reservoir for working the great water-wheel of these works. At the beginning of the present year, 765 males and 121 females were employed at the Primrose works. Attached to the works is a farm of 80 acres, supplied with manure by means of sewage refuse, which would otherwise contaminate the streams. The chief proprietor of these works is one of our most accomplished manufacturers. No calico-printer in this country has done more to study the chemistry of colours, and the application of taste to the production of designs.

There are four cotton factories at Clitheroe, which at the beginning of 1850 employed 556 males and 1,117 females. Nearly one third of the total population of Clitheroe, adults and children, are employed at the five large establishments.

The Bolton and Blackburn Railway has recently (June 1850) been extended to Clitheroe.

CLOA'CÆ, were large arched drains or sewers, formed under the streets of some ancient Roman cities. The most remarkable were the cloacæ of Rome, large portions of which still remain, and which were doubtless of high antiquity.

The cloacæ of Rome consisted of several branches, which ran in the low parts between the hills; these branches fell into one very large arched drain, constructed of solid blocks of stone, called the Cloaca Maxima. A portion of this cloaca is visible near the arch of Janus. The arched drain of the Cloaca Maxima is fifteen feet wide, and thirty high (these dimensions include the masonry), with three arches in contact one within another: in some parts there are raised paths along the sides of the cloaca; and in the walls are stone brackets to support the ends of the waste pipes of the fountain. The only cloacæ or drains for a city, which can be compared with the cloacæ of Rome, are the sewers of London.

The maintenance of the Roman cloacæ was originally the business of the censors, but afterwards belonged to the ædiles. Agrippa, during the ædileship, made numerous large cloacæ. The city of Pompeii had cloacæ on a smaller scale.

CLOCK AND WATCH MAKING. The first author who has introduced the term *horologium* as applicable to a clock that struck the hours appears to be Dante, who was born in 1265 and died in 1321. It would appear from this, that striking clocks were known in Italy as early as the latter part of the thirfeenth or beginning of the fourteenth century. There is known to have been some such kind of clock at quite as early a period in England; but it is considered probable that the next following century produced the first clock properly so called, the term *horologium* having previously included many kind of time measurers. Many allusions to celebrated clocks, in France, Italy, Germany, and Holland, are to be met with, belonging to the fourteenth and fifteenth centuries. It is now believed that a regulated clock was not the invention of one man, but a compound of successive inventions, each worthy of a separate contriver.

There was a clock made in 1364 by De Wyck, for the Emperor of Germany, which had two pallets worked by a crown-wheel, and two weights on a lever to regulate the movement to time. In 1484 Walthus made a balance-clock for astronomical observations. In 1560 Tycho Brahé had four clocks which indicated hours, minutes, and seconds; the largest of which had only three wheels, one having 1200 teeth. In 1577 Moestlin had a clock whose beats enabled him to determine approximately the apparent diameter of the sun. At what time *watches* or small clocks were introduced, by the use of a mainspring instead of a weight as the moving power, is not known; but it is supposed to have been in the early part of the sixteenth century. Galileo's discovery of the isochronism of the pendulum paved the way for the introduction of pendulum clocks; and it is probable that both Galileo and Huyghens had constructed pendulum clocks before 1648, though some writers say that Richard Harris made a pendulum clock a few years earlier, viz. in 1641. In 1676 Barlow, a London clock-maker, invented the repeating mechanism by which the hour last struck may be known by pulling a string. Several artists followed in the same line, particularly Quare, in London, and Julien le Roy, Collier, Larçay, Thiout, &c., on the Continent.

Clocks were soon after this made to show not only mean but apparent time.

A London clockmaker named Clement invented in 1680 the anchor-escapement, which was a great improvement on the crown-wheel before in use; he also introduced the practice of suspending the pendulum by a thin and flexible spring. The next important improvement was the adjustment of the length of the pendulum to the varied effects of heat and cold. In 1715 George Graham, by substituting a jar of mercury for the pendulum-ball, succeeded in retaining the point of suspension and the centre of oscillation at the same distance from each other. The principal objection to this pendulum is its liability to breakage, of which its author felt the full force, and in consequence suggested the idea of the opposite expansions of different metals as a compensation for a pendulum. John Harrison immediately turned his attention to the subject, and, by dint of perseverance, overcoming all the difficulties of his humble and retired situation, not only astonished the world by his improvements in horological machines, but absolutely constructed with his own hands a timekeeper which determined the longitude within such limits as to procure him the parliamentary reward of 20,000*l*. Although the anchor escapement previously mentioned was a great improvement upon all that had preceded it, still it was subject to objections, not one of the least of which was that at every vibration a considerable recoil took place. The inconveniences of this escapement were however removed (about the same time with the invention of Harrison's pendulum) by Graham, who introduced what is called the dead-beat escapement, which is both simple and effective.

Eight-Day Clocks.—In an eight-day clock there are two barrels containing springs, one to give motion to the train of wheels called the *going* train, and the other to the *striking* train. The first of these springs gives motion to a wheel called the main wheel, which in its turn acts upon several other wheels, the time of rotation of which corresponds with that of the minute and hour hand. The last wheel of this system acts upon two little levers or pallets, which give an alternating motion to the pendulum of the clock. A *fusee*, which is a kind of spiral system of grooves, is fitted to the main wheel, and enables the main wheel to maintain an equable motion during the varying pulling force of the spring. All the above-named wheels belong to the *going* train. There is a somewhat similar train belonging to the *striking* action; but the teeth of the wheels, instead of being so cut as to facilitate the movement of two index hands, act upon certain pins and levers which move the hammer belonging to the bell; this part of the mechanism is exceedingly beautiful, especially when the clock strikes the quarters.

Once in eight days the clock is 'wound up,' which consists in coiling up the going spring very tightly in its barrel. In its efforts to uncoil itself, the spring forcibly pulls round the main wheel with which it is placed in connection; and the fusee causes this motion to go on pretty steadily and equably. As the main-wheel cannot rotate without moving the train of wheels to which it is connected, all these latter also rotate, with a velocity depending on the number of teeth which act on each other. In two of the wheels these numbers are so regulated that the wheels revolve in one hour and twelve hours respectively; and the axes of these wheels serve as axes for the minute and hour hands. Meanwhile the second spring gives motion to the second train of wheels, which are so connected with the going wheels as to enable the bell-hammer to be moved at the proper time. One of the many kinds of pendulum, concealed behind or within the clock, is set in motion by one of the wheels, and, by its isochronous or 'equal-timed' vibrations, tends to give regularity to the movements of the wheels generally.

Large Pendulum Clocks.—Turret clocks differ from other machines employed for measuring time, not only in their greatly superior size, but because such a clock is frequently required to indicate the time upon as many as four different dials, on the four external faces of the tower in which it is mounted. This is accomplished by placing the clock near the centre of an apartment, and causing the motion of the axis which under ordinary circumstances would carry the minute hand (which revolves once in an hour), to be transmitted by bevil-gear to a vertical rod, the opposite end of which carries a horizontal bevil-wheel nearly on a level with, and situated centrically with reference to, the four external dials. The motion of this central wheel is communicated by four vertical bevil-wheels of the same size and number of teeth, ranged round its circumference, to four horizontal rods, the opposite ends of which, passing through the several dials, carry the four minute-hands. At the back of each dial is a series of wheels and pinions, by which motion is imparted to the hour-hand, which revolves once in twelve hours. In a turret-clock, the moving power is supplied by the descent of a weight, regulated in the case of the movement, or going-train, by the oscillations of a large pendulum, and in that of the striking train by the resistance of the air to the rapid revolutions of a fly or fan set in motion by the wheelwork. Owing to the necessity for using a very heavy hammer to strike the hours in a church clock, the power required for working the striking-train considerably exceeds that of the going train.

Musical Chimes.—These require the addition of another train of mechanism, somewhat like that which constitutes the striking train. The mechanism of the chimes very nearly resembles, on a large scale, that of a musical snuff-box: levers, connected with hammers which strike upon a series of bells, being substituted for the springs which in the musical snuff-box are caused to vibrate by the projecting pins on the revolving barrel.

In the new Royal Exchange clock, made by Mr. Dent, many improvements have been introduced. There is a simple but strong cast-iron framing, which enables the several parts of the clock to be put together with less strain than usual. The wheels for the striking train are made of cast iron; more durable and less costly than the usual gun-metal wheels. The wheels of the going train, smaller and requiring to be more nicely adjusted than those of the striking train, are made of hammered brass. Hollow iron drums are used instead of wooden cylinders for the driving barrels, and wire instead of hemp or ropes for suspending the weights. It was required, by the terms of contract, that this most admirable clock should have a compensation-pendulum, and that it should be so constructed as not only to show perfectly correct time upon the dials, but also to tell it with accuracy by making the first stroke of the hour upon the bell true to a second. This object is attained by a beautiful arrangement of mechanism. In this clock has also been introduced a beautiful contrivance for maintaining the motion of the wheels during the time of winding up, which was invented a few years since by Professor Airy for the clock-work of the great Northumberland telescope at the University of Cambridge.

Pocket Watches. — A pocket-watch is very similar in principle to a good clock, except that the regulation of the former is by a balance and spring, and that of the latter by a pendulum. It would be a matter of some difficulty to determine what artist first reduced the portable spring-clock to the dimensions of a watch to be worn in the pocket. The small clocks prior to the time of Huyghens and Hooke were very imperfect machines; they did not even profess to subdivide the hours into minutes and seconds until the invention of the balance-spring, which is to the balance what gravity is to the pendulum, and its introduction has contributed as much to the improvement of watches as did that of the pendulum to clocks. The honour of this invention was warmly contested by the last-named individuals previous to 1658; but, so far as priority of publication is concerned, the honour is due to Hooke.

When clocks and watches had acquired a certain degree of accuracy in their performance, the time lost in winding up (especially when it had to be done every twenty-four hours) became a matter of importance, and there have been several inventions to remedy this evil. By Huyghens the clock was kept going while winding up by means of an endless cord. The *forcing spring* gives another plan, in which a lever is so adjusted as to allow the wheels free movement, while the spring barrel is being acted on by the key. But Harrison's contrivance for the same purpose is the one now in general use, both in clocks and watches, and is admirably adapted to the purpose, as it requires no attention from the person who has to wind up the machine, but is always in its place, and ready for action the moment the operation of winding is commenced. It is generally called the *going fusee*, but a better name for it is *maintaining power*. The principle of its action depends on the mode in which the fusee is fixed into a socket connected with the main wheel, so as to allow the wheel and the fusee to rotate independently of each other when required.

The word *escapement* is a term applied to a combination of parts in a clock or watch, which has for its object the conversion of the circular motion of the wheels into a vibratory motion, as exhibited in the pendulum. The component parts include the scape-wheel, the pallets with their arbor or axis, and a bent lever attached thereto, called the crutch, which last piece maintains the motion of the pendulum. In a watch this combination consists of the scape-wheel, together with all those parts lying between it and the balance, and which are concerned in converting the circular motion of the wheels into the alternating one of the balance. The pallets act upon or between the pointed teeth of the scape-wheel by a reciprocal or oscillatory motion.

In a common *Vertical Watch*, the barrel containing the spring is near one edge; and next to it is the fusee. The spring within the barrel, formed by a narrow strip of highly tempered steel, is fastened at one end to the interior of the barrel, and at the other to the axis or arbor of the barrel. A fine steel chain runs from the exterior of the barrel to the exterior of the fusee; and, when the watch is wound up by the application of the watch-key to the arbor of the fusee, the chain is drawn from off the cylindrical surface of the barrel, and wound on the grooved surface of the fusee. In this process the spring within the barrel becomes coiled round very tightly; and, it is the recoil or resistance of the spring which slowly pulls the chain back again to the barrel, and causes the fusee to rotate. The fusee is concentric with a toothed wheel, whose teeth act upon those of a second wheel, and those upon a third, and so on throughout the delicate machine: one wheel rotating with such a velocity as to enable an index hand upon its axis to mark hours, another minutes, another (in a seconds-watch) seconds, and another to act upon the regulating or pendulum apparatus.

One of the chief distinctive features in watches, and the one by which the name or designation is often determined, is the nature of the escapement. The *duplex* escapement so named from a French watchmaker, is much more intricate than the escapement of a common vertical watch. A *vertical watch* has the escapement perpendicular to the face of the watch, while a *horizontal watch* has the escapement so formed parallel to the face of the watch. A *lever watch* has an escapement differing from all the others, which is preferred to those of either the vertical or horizontal watch. Earnshaw's *detached escapement*, intended chiefly for chronometers, is considered to excel all others for the accuracy of its performance.

The term *repeater*, or *repeating watch*, is applied to those watches which, in addition to showing the time on the dial, are supplied with mechanism for giving audible indication of the time when required. In an eight day spring clock, the number of blows given by the hammer to the bell corresponds with the hour denoted by the hand of the clock; and there is an arrangement by which the pulling of a string may be made to denote the hour *last* struck. But, from the peculiar mechanism involved, there are about ten minutes in every hour during which this repeating could not be produced. The filling up of this deficiency is an object in a repeating watch or clock. Some of these watches strike only the hours and quarters; while others, called minute repeaters, strike the minutes also. In a common watch, the wheels and pinions which are placed between the frame-plates constitute the *going train;* while the wheels and pinions placed between the uppermost frame-plate and the dial, serving to communicate the motion from the centre wheel to the index hands, constitute the *motion-work;* but, in addition to these a repeating watch has another system of mechanism, called the *repeating train*, for the purpose of transmitting the movement from the motion-work to the hammers which are to strike the hours and quarters.

Many interesting novelties have been introduced within the last few years, in respect to clocks and watches.

Trinity Church at Hull is believed to have the largest clock in the world with four dials or faces. Each dial is 13 feet in diameter, and each pair of hands weighs 56 lbs.

A useful kind of kitchen clock was described a few years ago by the late Mr. Loudon. It had a bell which called the attention of the cook at certain prescribed periods. Whether it were to boil an egg, or to perform any other kind of cooking which required a certain definite number of minutes, the cook moved an index hand on the face of a dial; and when the allotted time had expired, an alarum or bell rang to announce the fact.

Many of our churches and public buildings have clocks of which the faces are illuminated at night. The Horse Guards' clock was thus first illuminated in 1839, by the rays from a bude-light falling on the surface. It has, however, been frequently felt that the mode of illuminating public clocks is not such as to enable the hands to be visible for any considerable distance; the direction of the hands is the one important point in the indications of a clock; and if this be made distinct, the illumination of the clock generally may be in considerable part dispensed with. Mr. Hughes of Liverpool introduced a new method in that town in 1844, and published a small pamphlet relating to it. His plan consists in illuminating three points only; viz. the centre of the clock, and the outer extremity of each of the two hands. A stream of gas is conveyed into the spindle or shaft on which the hands are fixed, and thence to the hands themselves; and there are three orifices or jets where this gas is ignited. In the centre is a red light; at the outer extremity of the short hand is a green light; and at the outer extremity of the long hand a white light. The white and the green lights revolve with the hands round the dial plate: the white being always the farthest distant from the central stationary red light. A little consideration will show that this is quite sufficient to make the time intelligible; for in looking at an ordinary clock or watch, we are more guided by the *direction* taken by the two hands, with respect to the centre, than the figures towards which the ends of the hands point. It can be seen from a much greater distance than the ordinary kinds of illuminated clocks; and if it be at first not quite so intelligible, it might easily be made so by a few illuminated markings or figures round the circumference of the dial.

A curious circumstance is observable at nearly all our railway stations. If a train proceeds eastward or westward, the change of longitude produces a change in the proper time at the successive stations. If the station clocks show time corresponding to their longitudes, it would make the time-tables very confused; and the pocket watch carried by a passenger would never correspond with the station clocks, except at the town from which his watch is adjusted. But if, on the other hand, all the station-clocks shew Greenwich time (which is the plan adopted throughout Great Britain), then those clocks will not and do not correspond with the church-clocks and pocket-watches of the several towns, and much miscalculation of time results. Mr. Pilbrow has suggested an ingenious mode of obviating these difficulties, by having a clock which shall shew double time; and a clock so suggested has been constructed by Mr. Fairer of Tottenham. The arrangement is very simple: differing from the common clock only in the construction of the long or minute hand. This hand is shaped like the sector of a circle, corresponding in size or the number of degrees to the number of minutes in the difference between Greenwich time and the time at any particular station. The curved part of the hand is made of glass, so that the figures can be read through it. One edge or corner of the sector will mark Greenwich time, and the other edge the time at the station; so that the relation between the two will be instantly observable.

A singular kind of clock was registered in 1849 by Mr. Tanner, for shewing time adapted to places in five different longitudes. There is one large dial plate, with four smaller dials disposed equidistant upon it. The large dial has hour and minute hands, figures, &c., like an ordinary clock; while each small dial has its own set of figures and hands. The large dial shews Greenwich time; while the four small dials may be made to shew the time at four different places in any part of the world: differing from Greenwich time according to the differences of longitude. The mechanism of the clock is so adjusted as to shew Greenwich time on the large dial, while a train of toothed wheels and pinions transmits motion from the central clock to each one of the four small dials: the index hands being arranged 'fast' or 'slow,' according as the place to which the small dial refers lies east or west of the meridian of Greenwich.

An ingenious clock was made by Ratrenhofer of Vienna, in 1840, which shewed the time for 73 towns in different parts of the world, according to their longitudes. It had a dial-plate 14 inches in diameter, in the centre of which was the dial for Vienna; and around this dial were arranged 72 very small dials for the other towns; the Vienna dial or clock was set to work by the descent of a 4 lb. weight; and the other 72 dials were moved by wheels connected with the Vienna dial; so that one winding up set the whole in motion. All the 73 dials shewed different time, according to the longitudes of the towns to which they were respectively adjusted.

From a Report made by M. Francœur to a committee on the Mechanic Arts of the So-Societé d'Encouragement, in 1839, it appears that the French clock makers have endeavoured to produce church clocks at a much lower rate than they could be constructed in former times, by the adoption of the manufacturing system rather than the handicraft system: that is, by making considerable numbers of each kind at once. There is at Moret a manufactory of what are called *Jura Clocks*, in which all the pieces of the mechanism are made in the large way and all made to fit; wheels, weights, bells, dial plates, hands, hammers, &c., are made, set up, and delivered in the market for about forty francs the set. One of these low-priced clocks is taken, and a few changes made in it to fit for the tower of a church, by using larger hammer, bell, dial, and hands. According to the report of M. Francœur, as quoted in the *Annales des Mines*, the result is much cheaper than if a single clock were made throughout on the usual system.

French clocks, many of which exhibit great beauty of form (though we believe they are scarcely considered to equal English clocks in solidity and durability of construction) were imported in 1849 to the value of 65,000*l*.

The Clock and Watch Manufacture exhibits many remarkable features. The large clocks for public buildings are made by a very small number of firms, on account of the demand being limited and the duration of the clocks considerable. Nearly all the watch-makers of London live in one district—Clerkenwell; but even these, great as is their number, do not make the wheel-work for the watches; these works, or *movements*, as they are called, are nearly all manufactured in Lancashire, where they can be produced cheaper than in London. There are no watch-factories in Clerkenwell; but there are thirty or forty distinct classes of tradesmen, comprising perhaps three times that number of minor subdivisions, all living and working at their own homes, most of them having aid from apprentices or journeymen, and all employed at some one or other of the numerous parts of a watch. A *Watch Manufacturer*, in the Clerkenwell sense of the term, makes none of these parts, but puts them all together when others have made them.

CLONMEL is one of those towns to which Ireland may fairly look as seats of her future prosperity, whenever that prosperity shall arrive. For the last 20 years Clonmel has been steadily advancing in prosperity. 'It is,' says Mr. Inglis,' writing in 1834, 'the great point of export for Tipperary, which is one great granary, as well as for parts of other counties, for it is the first point at which water-carriage commences.' The exports are chiefly corn, bacon, and butter; of wheat from two to three hundred thousand barrels are annually brought into the town. The flour mills are very numerous and extensive. They are chiefly situated on Suir island. The bacon trade was also very extensive until within a few years. The butter trade, though large, has also lately been on the decline. Another considerable source of employment is the great posting establishment of Mr. Bianconi, of which Clonmel is the depôt. There are also several breweries, and an extensive distillery in the vicinity; and a cotton manufactory, which employs about 200 persons. There is consequently little want of employment. The carrying trade of the town is conducted by barges of from 20 to 40 tons which ply on the Suir to Waterford: of these there are about 120 on the river. The northern bank of the Suir, between the two lower bridges, is quayed in. The Waterford and Limerick Railway now in progress passes through Clonmel.

CLOVER was introduced into the agriculture of Great Britain about the 16th century, from the Low Countries, where it had been long cultivated as green food for cattle in situations where natural pastures were scarce. The species of clover are annual, biennial, or perennial plants. The most approved variety of the biennial clovers is the common *red* or *broad clover*, which is usually sown with barley or oats, or sometimes among wheat or rye in spring. In Scotland clover is often sown among wheat, in Norfolk invariably with barley, and in Belgium among rye. It is usual to sow *rye-grass* in a small proportion with clover seed, especially where clover, having been often repeated on the same land, is apt to fail. A very extensive use of clover-hay in London is to cut it into chaff, and to mix this with oats and beans for dray horses, which have little or no hay given them in any other way; but the most profitable use of clover is to cut it green for horses and cattle. The *white* or *Dutch clover*, the *cow-grass*, the *yellow trefoil*, and the *hop trefoil* are all usefully employed as fodder. The only annual clover which is cultivated is the *French clover*, a most valuable addition to the plants usually sold for fodder, from the short time in which it arrives at perfection if sown in spring; so that, where clover has failed, this may be sown to fill up the bare places.

On good land, an acre of clover will produce as much as three tons and a half of dry hay; that is, two tons the first cutting, and one and a half the second. Greater crops are obtained on very highly manured land.

Clover seed was imported to the extent of 99,813 cwts. in 1848.

CLOVES. The cloves of the spice-shops are the flower-buds of the *Caryophyllus Aromaticus*, gathered before they open, and dried in the sun. The tree is a native of the Molucca, whence it has been carried to other tropical countries. The name *clove* is a corruption of the French word *clou*, a nail, a name that has been suggested by the resemblance of the dried clove to a nail. The aromatic stimulating effects of cloves are well known.

By distillation a thickish oil is obtained, which is at first colourless, but by time becomes yellow and brown. Its taste is very fiery and aromatic; it reacts as an acid. In time there separates from it a stearopten, or clove-camphor, called *caryophyllin*.

Cloves are employed in medicine, and also more extensively for culinary purposes. When received into the stomach they are powerfully stimulant, and promote digestion when taken along with food which is insipid or difficult of digestion. Oil of cloves is used much in medicine.

Cloves were imported in 1849 to the extent of 274,712 lb.

CLYDE. Below Glasgow the Clyde has been made the scene of astonishing engineering works. About 80 years ago, only vessels of 3½ feet draught could come up to Glasgow Bridge; in 1775 the whole river from Glasgow to Dumbarton was deepened so as to receive vessels of 6 feet draught: this depth was increased by 1831 to 13½ feet; by 1847 to 15 feet; and works now in progress will carry the depth to 20 feet at neap tides. The river for 12 miles is being widened, straightened and deepened.

A suggestion of a singular kind has been recently thrown out, in the pages of the *Glasgow Advertiser*, concerning the forthcoming Industrial Exhibition. "There is at the present day in Glasgow, we believe, in the hands of Messrs. Claud, Girdwood, and Co., or their successors, the very identical steam-engine that Henry Bell fitted on board the *Comet*, the first steamer that ever sailed on the Clyde —the vessel, in fact, which may be called the precursor of the splendid steamers that now circumnavigate the globe, and bring the antipodes, as it were, to our very threshold. This steam-engine has on several occasions been exhibited in Glasgow, and has always been an object of much attraction, as properly it should be, to those who know the value of such a wonderful invention as that of the marine steam-engine. Mr. John Wood, of Port Glasgow, the veteran ship-builder who laid the keel of the first passsage steamer that navigated the Clyde—the father of all the wonderful steamships that now exist—possesses the draft, and, if required, could even at the present day produce an exact counterpart of the Comet. Now, what we would propose as a source of attraction at the Exhibition of 1851, is that an exact duplicate of the Comet should be built by Mr. Wood, and that it should be fitted with the original steam-engine of that vessel, so as to present an exact counterpart to that eventful steamer as she sailed on the river Clyde in the year 1812. The expense of such an undertaking would be a mere bagatelle."

COACHES AND COACH-MAKING. It is stated by Stow, that in '1564, Boonen, a Dutchman, became the queen's coachman, and was the first that brought the use of coaches into England.'

A long time elapsed before this luxury was attained by more than a few very rich and distinguished individuals, and a very much longer time before coaches became general. Coaches let for hire were first established in England in 1625; they did not stand in the streets, but at the principal inns. In 1637 there were, in London and Westminster, 50 hackney-coaches. Stage-coaches were first used in England soon after the introduction of hired carriages. The first mail coach travelled from London to Edinburgh about 1785, and to Glasgow in 1788.

The use of stage-coaches rapidly extended itself; and from the latter part of the last century, until the establishment of railways, there was scarcely any small town through which some stage coach did not pass, and no considerable road which was not travelled by many. In this country the best stage-coaches were very perfect machines, and the arrangements by which they were conducted, when the number of persons and animals that were engaged is considered, were extremely complete. The principal stage-coaches ran with four horses, and the rate of travelling among the *fast* coaches was rapid. In 1833, the distance between London and Shrewsbury (154 miles), Exeter (171 miles), and Manchester (187 miles), was done in a day. The mail to Holyhead did the 261 miles in 27 hours, and that to Liverpool, 203 miles, in 21 hours. The coaches were on springs, and, though strong, were light and elegant.

The omnibus, a sort of long-bodied coach, was introduced into London in 1831. We shall have some details to give in a later article, concerning the hired vehicles of London. [OMNIBUSES AND CABS.]

The coaches which form the trains upon railroads are of very different construction from those used on common roads; they are stronger, larger, and heavier: they are fastened together with links of chain, and there is attached to the back and front of each a 'fender' by which concussion is prevented when the train is stopped.

Upon the Continent, travelling in public carriages was never so rapid or so commodious as in England. In France the diligences were, and those which still exist are, clumsy carriages, generally consisting of three bodies, and are drawn by five or six horses, usually driven by one postilion from his saddle. The first body, called the 'coupé,' formed like a chariot, contains three people; the second, which is like a coach, the 'intérieur,' holds six persons; the third, which is similar to a coach turned sidewise, carries six or eight passengers, and is called the 'rotonde.' In addition to these, there is on the roof, before the place appropriated to the luggage, the 'banquette,' a bench sometimes furnished with a hood for the accommodation of four passengers. But every where the use of the railroad is superseding the old stage-coach on all the great lines of road in all highly civilised countries.

In the making of coaches or carriages, as a highly skilled department of manufacture; the timber, the iron, the leather, the brass and plated metals, the trimmings, and other materials, are wrought by wholly distinct bodies of operatives; and there are many minor divisions of each class. The 'body-makers' produce the vehicle or body itself, while the 'carriage-makers' are employed on the stouter and stronger timbers beneath and around the body. The chief kinds of wood employed are ash, beech, elm, oak, mahogany, cedar, pine, deal, fustic, birch, and larch—each kind appropriated to the purpose for which its fibrous nature best fits it. In working up these varieties of timber, tools and processes are employed similar to those in cabinet-making, together with others peculiar to coach-making.

The various forms of the coach, gig, dennet, curricle, tilbury, stanhope, &c., lead to the exercise of much ingenuity in fashioning the wood-work to the requisite curved forms. The axles on which the wheels work, the springs which protect the carriage from concussion, and the iron perch which is sometimes used instead of wood, are the work of the 'coach-smith,' one of the most highly paid classes of London workmen. The coating of the body of the coach with leather is a most difficult and delicate art; and the subsequent painting, trimming, and decorating, all rank among the highest kinds in their respective classes. Coach-axles have been made the subject of patents; and so indeed have many other improvements in the manufacture of parts of coaches. So far as regards workmanship and processes, carts and waggons bear almost the same relation to coaches that carpentry does to cabinet-making; similar in character, but coarser.

COAGULATION is the solidification of a liquid produced without evaporation and without crystallisation.

COALS AND COAL MINING. We shall here treat in succession of the *formation of coal*, the *coal fields*, *coal mining*, and the *coal trade*,—giving a few brief details under each heading.

Formation of Coal.—From the presence of tree-ferns, and palms, and other plants which now grow in tropical climates, in coal, it has been inferred that at the period at which the coal-beds were deposited the temperature of these parts of the world at least was much greater than it is at present. If the facts we actually possess are soberly examined, they amount to these :—

1. That coal is of vegetable origin.

2. That at the period of its deposit the earth was covered with a rich vegetation, of which only a small portion has been preserved, and that of this portion all the species and several of the races are totally unknown at the present day.

3. That the climate may possibly have been something milder than it now is, but that there is no evidence in the vegetable kingdom to show that it was materially different from that of the present day.

From these data it is assumed that coal is the result of vegetable substances which have been pressed down through unknown ages into a compact mass, which has passed through the intermediate stage of peat or bog, and become gradually consolidated into coal.

The report of Sir H. De la Beche and Dr. Lyon Playfair, on the quality of coal best suited for the steam navy, contains much valuable information on the different kinds of coal, and their heating effect. One kind will raise steam very quickly; another is slower in its action, but generates a greater abundance of steam. Two kinds may be equal in these respects, yet one would speedily crumble by stowage, while the other would remain unbroken. Some kinds occupy much less bulk for a given weight than others. All these points being of importance, it has been the desire of the Admiralty to ascertain which kind of coal possesses the greatest number of advantages, and the fewest disadvantages, in respect to steam navigation. The commissioners constructed apparatus, especially calculated to further the enquiry; and experimented on thirty varieties of coal. Among the data ascertained were—the number of pounds of water evaporated from an initial temperature of 212°, by one pound of coal; weight of one cubic foot of the coal, as used for fuel, and as calculated from the specific gravity; space in cubic feet occupied by one ton; cohesive power of the coal; weight of water evaporated from 212° by one cubic foot; rate of evaporation, or weight of water evaporated in one hour; chemical constituents of the coal, in carbon, hydrogen, nitrogen, sulphur, oxygen, and ash; per centage of coke after coking; weight of water that can be raised from 32° to 212° by the heat of one pound of coal; per centage of the various products of combustion, in coke, tar, water, ammonia, carbonic acid, sulphuretted hydrogen, olefiant gas, &c.; and the force generated or weight that could be raised to the height of one foot by the combustion of one pound of coal.

The commissioners show that fuel for war-steamers ought to raise steam quickly; to possess high evaporative powers; to contain but little bitumen; to possess considerable cohesion among the particles; to have density and closeness of structure; to contain but little sulphur; and to have no liability to decay during storage. The kinds brought to the test of experiment shewed, as might be expected, very different results under these several headings; insomuch that no one kind stood first on the list in respect to more than two or three of the above qualities. Three kinds of patent fuel, formed by admixtures of coal dust with bituminous and other substances, were included among the varieties examined; and it was found that Warlich's patent fuel stood higher than any kinds of coal in respect to many qualities. The commissioners expressed an opinion that it might be practicable to produce a composite coal, or

KNIGHT'S CYCLOPÆDIA OF THE INDUSTRY OF ALL NATIONS.

No. 16.

a mixture of many kinds of coal, which would possess a more useful aggregate of qualities than those possessed by any one sort of coal *per se;* and they recommend further experiments as a means of putting this plan to the test. As an example of their mode of stating the evidence for and against any one species of coal, we may take Anthracite:—"It has a very high evaporative power; but not being easily ignited, it is not suited for quick action. It has great cohesion in its particles, and is not easily broken up by attrition; but it is not a caking coal, and therefore would not cohere in the furnace when the ship rolled in a gale of wind. It emits no smoke; but from the intensity of its combustion it causes the iron of the bars and boilers to oxidate or wear away rapidly."

Coal Fields.—These are large accumulations of coal which exist in various parts of the world. Coal is found in these fields in strata of various thickness, alternating with slate-clay and sandstone; the alternations being frequently and indefinitely repeated. The coal beds, which are of various qualities, are principally distinguished by the proportion of bitumen in the coal. The coal-seams, together with their alternating strata, called the *coal-measures*, usually lie on beds of millstone grit and shale (hard coarse-grained sandstone and slate clay), which sometimes exceed 120 fathoms in thickness. Under this series is the mountain or carboniferous limestone, an assemblage of calcareous strata, of variable thickness, sometimes exceeding 900 feet. The carboniferous limestone rests on a bed of old red sandstone, varying in thickness from 200 to 2000 feet. These four different series of strata are usually comprehended under the term 'coal-formation.'

The coal-fields of Great Britain are very numerous and deserve to be studied somewhat in detail. The Northumberland and Durham coal-field commences near the mouth of the river Coquet on the north, and extends nearly to the Tees on the south. Its greatest length is 58 miles, and its greatest breadth about 24. The beds of coal in some places appear at the surface, while in the opposite direction they are at great depths. The beds of these coal-measures are about 80 in number, and consist of alternating beds of coal, sandstone, and slate-clay; making an aggregate thickness of 1620 feet, which varies however in different parts. The aggregate thickness of coal is supposed to be about 44 feet, of which about 30 feet are workable. This coal is shipped in immense quantities from the Tyne, the Wear, and the Tees. There is another coal-formation, which extends through parts of Durham, Northumberland, and Cumberland, independent of the former.

In Yorkshire there are detached coal-fields, very limited in extent, being small insulated coal-basins, lying in hollows in the gritstone. They occur near Middleham, Leyburne, Thorpefell, near Burnsell, and as far west as Kettlewell. Southward of these is an extensive coal-field, which occupies an area extending north and south from a little to the north-east of Leeds nearly to Derby, a distance of more than 65 miles; its greatest width, 23 miles, is on the north, reaching nearly as far as Halifax to the west. The strata of this coal-formation are very numerous; the coal-seams are about 30 in number, varying from 6 inches to 11 feet in thickness. Since the opening of the Midland Railway, which traverses this coal-field, the working of the collieries has been vastly extended by the facilities for inland carriage. In north Staffordshire there are two detached coal-fields: the one situated on the N. E. of Newcastle-under-Lyme, distinguished as the Pottery Coal Field; the other at Cheadle, to the east of the first. The first measures from 6 to 10 miles in every direction; the second, from 3 to 5 miles. Thirty-two beds of coal have been met with, from 3 to 10 feet thick, and at depths from 50 to 400 yards. The South Lancashire coal-field forms an area somewhat in the shape of a crescent, having Manchester nearly in the centre; and northward of this are the North Lancashire and the Whitehaven beds; in the latter, some of the seams are very thick and of the finest quality; the shafts are very deep, and some of the mines are worked under the sea.

The South Staffordshire coal-field is about 20 miles long by 7 broad. Many coal-seams, of eight, six, and four feet in thickness, are worked in the northern portion of this field; but the southern portion is of much more importance, as it contains seams from 30 to 45 feet in thickness. This enormous thickness is however not one continuous seam, but a number of seams, divided by layers of what the miners call *band*, which are very thin beds of clay-slate. The working of these thick seams is not so profitable as might be supposed. The pillars left standing in order to support the high roof are estimated at about one-third of the whole coal in the bed, and the small coal left in the mine is about equal to another third, so that only one third of the whole is at present taken out of the mine. This district supplies coal to the numerous iron-works in the immediate neighbourhood, and the manufactories of Birmingham and its vicinity; besides which, all the neighbouring counties, as far south as Reading and Gloucester, are supplied by means of inland navigation. Leicestershire and Warwickshire have small coal fields, independent of the one here noticed.

In North Wales, a valley crosses the Isle of Anglesea, parallel to the Menai Straits, and is flanked on both sides by parallel bands of carboniferous limestone. Coal of good quality exists here, and a few mines have been successfully opened. In Flintshire a coal-field exists, extending north and south from the Dee to Oswestry, about 30 miles: not continuously however, but in patches. It is supposed that the seams pass under the Dee, and join those of Lancashire. The Coalbrook Dale coal-field is composed of the usual alternating strata, and comprises nearly 90 alternations; the seams vary from a few inches to 5 feet in thickness; they occur at depths from 100 to 700 feet.

The coal-field of South Wales is upwards of 100 miles in length, and the average breadth in the counties of Monmouth, Glamorgan, Caermarthen, and part of Brecon, is from 18 to 20 miles; it becomes much narrower in Pembrokeshire, being there only from 3 to 5 miles. This area extends from Pontypool on the east, to St. Bride's Bay on the west, and forms a vast basin of limestone, in which all the strata of coal and ironstone are deposited. The lowest bed is 700 fathoms deep at the centre, and all the principal strata lie from 500 fathoms deep to this depth. But this district is intersected by deep valleys, which generally run in a north and south direction, intersecting the coal. By driving levels in the hills, the beds of coal are found without the labour and expense of sinking shafts; there are also many pits in the low valleys. The seams vary from a few inches to 9 feet in thickness; and their aggregate thickness is about 100 feet. On the south side of the basin, the coal is principally of a bituminous nature; on the north-east it is a coking coal; on the north-west, stone coal. The occurrence of rich iron ore with or near the coal has led to the establishment of vast iron-works in South Wales.

The Gloucester and Somerset coal-field is about 25 miles long by 11 wide. The seams of coal are very thin in comparison with those which are worked in the principal coal-fields of England, and in most of those would be rejected as not worth the working. The Forest of Dean contains a coal-field about 10 miles long by 6 wide.

The principal coal-district of Scotland occupies the tract which forms the great central lowland of Scotland, and lies between the great transition chain on the south, and the still loftier primitive mountains of the Highlands on the north. In the county of Haddington are three seams of good workable coal. There are a few mines in Fifeshire and Mid-Lothian. In Lanark the coal-fields are numerous and extensive. Throughout this district seven seams of coal are usually found within 415 feet of the surface; five of these seams are of sufficient thickness to be wrought, and of good quality. Coal is found in various other parts of Scotland.

Coal has been discovered in more or less quantity in seventeen counties of Ireland. The Munster coal-district occupies a considerable portion of the counties of Limerick and Kerry, and a large part of the county of Cork; it is by much the most extensive in Ireland. Coal and culm have been raised for near a century in the neighbourhood of Kanturk, in the county of Cork. At Dromagh colliery the work has been carried on to a very considerable extent; and the beds found in it are of four kinds, the ***Coal-Bed***, the ***Rock Coal***, the ***Bulk-Bed***, and ***Bath's Bed.*** The greatest depth of the Munster collieries is about 80 yards.

On the continent of Europe coal-fields are very irregularly scattered. They occur abundantly in Belgium. In Saxony and Bohemia coal is found; and in less quantity in Russia, Sweden, and Spain. France has many coal-fields, but the produce is not enough for her consumption. There were 425 coal mines in France in 1844, of which however only 252 were worked, employing 30,000 persons.

Asia contains a little coal in China, Birmah, India, and Persia. Coal has been found abundantly both in Australia and Van Diemen's Land. America, according to recent discoveries, seems to be richer in coal than any other part of the world.

Mr. Taylor, in his valuable 'Statistics of Coal,' says that the ascertained areas of the coal-fields of various countries are as follows:—

United States	133,132 sq. m.
British America	18,000
Great Britain	11,859
Spain	3,408
France	1,719
Belgium	518

But the actual yearly production, and bringing to market, form a remarkably different series:—

Great Britain	31,500,000 tons.
Belgium	4,960,000
United States	4,400,000
France	4,140,000
Prussia	3,500,000
Austria	700,000

Coal Mining.—The thickness of workable beds of coal may be said generally to vary from three or four to eight or nine feet, although sometimes, when several seams come together without any intervening layers of rock, they may expand to twenty or thirty feet, of which we have an example in the 'ten yard coal' of Staffordshire. In every coal-field there are many seams of coal at greater or less intervals, one below another, of which as many as three or four are frequently worked in the same mine.

When the position of the beds of coal has been discovered, the first process is to sink a perpendicular shaft from the surface so as to intersect the various strata containing the coal, and of course as many of the beds of coal as are considered to be worth working. The upper portion, as far down as the solid rock, is either bricked or walled, and where the ground is weak this casing may be continued throughout. On reaching the first workable seam of coal, the sinking of the pit is for a time suspended, and a broad straight passage termed a 'bord' or 'gate' is driven from it upon the seam of coal in opposite directions. The breadth of this passage is usually twelve or fourteen feet, and it is formed the whole height of the seam of coal, so as to expose the stratum above, which is called the 'roof,' and the one below, which is termed the 'thill,' and its direction is always arranged so as to follow the cleavage of the coal which forms its sides, which thus presents a clean uniform surface. When the principal bord has proceeded some distance on both sides of the pit, narrow passages, termed 'headways,' are driven from it at regular intervals, and exactly at right angles; and when these have proceeded eight or ten yards, they are made to communicate with another bord, which is opened parallel to the first and on each side of it. Thus the operations continue, until the mine resembles a town of streets rectangularly arranged. The water encountered in the above operations is drawn to the surface by a steam-engine erected at the top of the shaft, which is so arranged as also to raise the coal and rubbish, for which purpose either 'corves' or baskets are commonly employed. In small coal mines the ventilation is managed by separating a portion of the shaft from the larger part by an air-tight boarding, which is carried down to the bottom; but in large coal-mines another shaft is sunk at some distance from the first, and when the communication between them has been effected, the one being made downcast and the other upcast, the air is made to pass through the whole of the passages.

While the workings on the first seam of coal are thus going on, the shaft may be sunk to a second or third seam, where similar operations will be commenced, small underground pits or 'staples' being sunk at intervals from the workings on the upper seam to those on the seam below, by which ventilation will be promoted.

The mode in which the pitman proceeds in excavating the coal is by cutting a narrow fissure on the seam on each side of the bord with his pick-axe, and undermining the coal between, and then cutting into and forcing down the isolated portion of coal, or, where the seam is thick, by detaching the great cubical mass thus prepared by blasting, two or three shots being sometimes simultaneously fired at the top of the seam. From 60 to 80 or 100 tons of coal may thus be brought down at once, when it is put into corves, drawn along a tram-road to the shaft, and thence raised by a steam-engine to the surface, where it is often passed over gratings or 'screens' in order to separate the small pulverised coal from the larger masses.

In mines which are not endangered by explosive gases or 'fire-damp,' the coal-miner or 'pit-man' is guided in his operations by the usual subterranean light—a small candle stuck into a piece of moist clay; but where the fire-damp is apprehended the safety-lamp is used. [LAMP, SAFETY.]

The frequency of colliery accidents has recently drawn the attention of scientific men to the subject; and the Institute of Civil Engineers is at the present time engaged in the discussion of schemes for improved systems of ventilation.

Coal Trade.—It was long considered politic to check the exportation of coals to other countries, both through fear of exhausting the mines, and because it was imagined that our superiority as manufacturers might be endangered. A heavy export duty was accordingly levied; but this was gradually lessened in 1831, 1835, and 1842, and abolished altogether in 1845. There was formerly a revenue on coals carried coastwise, but this was abolished in 1831.

A very peculiar regulation was established by the coal owners of the northern coal-field, called the 'limitation of the vend.' It was a systematic combination among the owners of collieries having their outlets by the Tyne, the Wear, and the Tees, to raise the price to consumers by a self-imposed restriction as to the quantity supplied. When the coal duty was abandoned in 1845 the coal-owners gave up the 'limitation of the vend.'

A regulation which affects the coal trade from the Tyne and the Wear has been established by act of parliament (1826), under the provisions of which every ship must be loaded in her turn; and, if any colliery refuse to sell, a penalty is imposed of 100*l.*; but this regulation may be and has been evaded by the coal-owners by an easily concocted pretext. Regulations have also been made as to the unloading of coal-vessels in the Thames: the number being guided by the price of coal in such a way as to keep up the monopoly.

In May 1844, the harbour-master of the port of London presented a return to the lord mayor, which shows the operation of the regulations established by the coal-owners in the port of London for keeping up the price of coal. On the first of May there were 260 vessels laden with coal, detained in sections waiting their 'turn' of sale. On one day in the same month, ten colliers had been detained, with their captains and crews, for 46 days, and two had been detained above 50 days. On the 27th of May, 109 coal-laden ships were detained in sections, and the price of the best coal had advanced to 24*s.* and 25*s.* per ton, or about 34*s.* per ton to the consumer.

The railways now in progress will have an important and most beneficial effect in reducing the price of coal in all districts lying far away from the collieries; indeed such influence has already been felt, since the year just named. The York and Berwick Railway, and the York and North Midland Railway, carry an immense quantity of coal; and the Great Northern Company have lately commenced to do the same.

In 1845, the collieries of Northumberland and Durham were 129 in number; the steam-engines employed were 19,204 horse-power; the actual production was 6,790,993 tons. In 1844 there were 16,515 persons employed at the Tyne collieries; 13,173 at those of the Wear; and 4211 at those of the Tees; making 33,899 in all. The largest number at any one colliery was 1403 at Lambton. The colliery proprietorships are ranged under four classes, according to the scale of the operations. The 1st class comprises four great concerns, headed respectively by the Marquis of Londonderry, the Earl of Durham, Lord Ravensworth, and the Hetton Coal Company. The capital sunk in each of these concerns is supposed to be not less than half a million sterling; they each comprise from six to twelve separate mines, and all the necessary engines, waggons, horses, &c.: and they are believed to realise a profit on an average from 35,000*l.* to 45,000*l.* per year each. The 2nd class comprises companies or partnerships whose sunk capital ranges from one to two hundred thousand pounds. The 3rd class includes those concerns which have only a single pit each, and whose capitals are from forty to sixty thousand pounds. The 4th class, humbler but more numerous than any of the others, comprises those which have a capital ranging from eight to thirty thousand pounds. In South Staffordshire, the 'Butty' system of employing miners is extensively acted on. This consists in the miners being the servants, not of the proprietor or lessee of a colliery, but of a contractor called a 'butty,' who engages with the proprietor of the mine to deliver the coal at so much per ton; hiring the labourers himself, using his own horses, and supplying all the tools necessary for working the mines. These butties have in general been working miners, who, by the accumulation of some little capital, or by the assistance of relations, are enabled to engage a pit, with or without partnership with other persons, and to enter into a bond to raise the coal at a given price per ton. But in the Northumberland and Durham district the relation between the proprietors and the miners is more direct and intimate. No middlemen or contractors are employed; the overseers, viewers, and other intermediate officers are paid by regular salaries; and the working colliers receive in cash from the proprietors, once a fortnight, the amount of their earnings.

The coal trade of England is one of great magnitude. The coal exported from the United Kingdom to foreign countries in 1849 amounted to 2,730,507 tons. The coal brought to London in the same year amounted to 3,380,786 tons. Of the quantity brought to London, about two-fifths are shipped at the Tyne, and nearly the whole of the remaining three-fifths at the Durham ports. Of the coal sent to foreign countries, about 600,000 tons, or more than one-fifth of the whole, is sent to France: our next best customers being Germany and Prussia, who together take about 450,000 tons.

The great towns of Lancashire, Yorkshire, Nottinghamshire, Derbyshire, Leicestershire, Warwickshire, and Staffordshire, are supplied by canals or by land-carriage from collieries in the respective counties here enumerated. It has been estimated that the iron-works of Great Britain, most of which are situated in spots were coal is found, require every year, for smelting the ore and converting the raw material into bars, plates, &c., nearly seven millions of tons. There is good reason for believing that the annual consumption of coal within the United Kingdom is not far short of 35,000,000 tons. In 1841 the number of persons in Great Britain employed in coal-mines was 118,233. In Durham there were in that year, on an exact enumeration, more persons employed under ground in coal-mines than in cultivating the surface.

Coal and the collieries will not be neglected at the forthcoming Exhibition of Industry. The coal-owners of Northumberland and Durham have deputed to a number of intelligent colliery viewers the preparation of a map of the coal district, showing the extent and outcrop of the different coal-beds, together with the faults and other remarkable interruptions—a section of a coal-field, from and to given points, north and south, and a similar section from east to west—a model in pieces showing the structure of a given portion of the coal-field—a synopsis of the coal-seams in illustration of the map and sections—a collection of the fossils found in the coal-strata—working plan of a colliery, exhibiting the system of working and ventilation—a model showing the system of ventilation—specimens of the strata properly arranged—materials, &c., employed in coal-mining—models of machinery, underground railways, engines, shafts, lamps, loading machinery, drops, &c.

A block of coal, of gigantic dimensions, has been raised from Hange Colliery, near Tipton, to be sent to the Exhibition. It is six feet high by eighteen feet in circumference, and weighs about five tons. It is supposed to be the greatest weight ever attempted to be drawn out of a coal-mine in one piece; and it is also a general opinion that no coal-field in Great Britain could yield such a large mass, except the 30 foot seam of South Staffordshire. The specimen is said to be remarkably fine, bright, and clear.

COALBROOK DALE. This small spot, situated in the eastern part of Shropshire, has acquired a manufacturing celebrity for the iron goods cast there; and this as a manufacture has depended in part on the existence of coal at the spot. The coal-field of the Dale is about 6 miles long by 2 broad, and contains 86 alternations of coal and other strata, which have been penetrated to a depth of more than 700 feet.

The Coalbrook Dale Iron Works have belonged to the family of Messrs. Darby for more than 200 years. Some of the earliest castings of great magnitude in this country—indeed we believe the earliest, were made here; and the works have ever since been celebrated for the delicacy and beauty of the smaller castings in iron. On a pleasant festive occasion in 1850, planned in compliment to the chief proprietor, the colliers, miners, and workmen of the Coalbrook Dale district generally, to the number of nearly 4,000, walked in procession through Horsehay, Ironbridge, Madeley, and Dawley, and ended the day with some of those displays of kindly feeling which are always so valuable in the relation between employers and the employed.

COBALT. This metal was discovered by Brandt in 1733, associated with arsenic and other metals. It has a reddish gray colour, and a weak metallic lustre; it fuses at a high temperature, and crystallises in cooling.

Cobalt is extensively employed in the Arts. Its oxide gives an intense and beautiful blue colour to glass, and is hence much employed in painting glass and porcelain; while the blue glass thus produced, when reduced to a fine powder, is called *Smalts* or *powder blue*, and is used for correcting the yellowish tint of paper and linen.

The nitrate of cobalt, when dissolved in water, forms a *sympathetic* ink, the traces of which become blue when heated, or green if iron be present. The acetate forms a sympathetic ink which becomes blue when heated. The phosphate of cobalt, combined with alumina, produces a blue colour almost as intense and beautiful as that of ultramarine: it is called *Thenard's* or *cobalt blue*.

Cobalt forms alloys with arsenic, antimony, tin, zinc, lead, gold, and platinum.

COCA, the dried leaf of *Erythroxylon coca*, is one of those stimulating narcotics which belong to the same class with tobacco and opium, but is more remarkable than either of them in its effects upon the human system. The plant is found wild in Peru, according to Pöppig, in the environs of Cuchero, and on the stony summit of Cerro de San Cristobal. It is cultivated extensively in the mild but very moist climate of the Andes of Peru, at from 2000 to 5000 feet above the sea: in colder sitnations it is apt to be killed, and in warmer districts the leaf loses its flavour.

The effects of this drug are said to be of the most pernicious nature, exceeding even opium in the destruction of mental and bodily powers. The coca leaf is chewed by the Peruvian, mixed with finely powdered chalk, and brings on a state of apathy and indifference to all surrounding objects. The desire for this drug increases so much with indulgence in it, that a confirmed coca-chewer is said never to have been reclaimed.

The immoderate addiction of the Peruvians to the use of this drug is such that their forests have long since ceased to be able to supply their wants; and the cnltivation of the plant has been carried to a very great extent, not only under the Incas but beneath the local government of the Spaniards, who seem to have been no more able to resist the temptation of a large revenue from the monopoly of this article than European nations from the consumption of ardent spirits. The cultivation of coca is therefore an important feature in Peruvian husbandry.

The exciting principle of the coca has so very volatile a nature that leaves only twelve months old become perfectly inert and good for nothing. Large heaps of the freshly dried leaves, particularly while the warm rays of the sun are upon them, diffuse a very strong smell resembling that of hay in which there is a quantity of melilot.

CO'CCULUS. Many species of this plant are usefully applied, chiefly in medicine; but that which is best known is the *Cocculus Indicus*, a native of East Africa. *Cocculus Indicus Berries* are the fruit of the *Cocculus suberosus*, or *Menispermum cocculus*. Besides being occasionally used in medicine, it is a poison which is used for destroying fish, and has also been extensively used by brewers as a substitute for hops—an adulteration which is prohibited in Britain by severe statutes. Cocculus Indicus is never used internally in the practice of medicine; but an ointment formed of the powdered berries is very efficacious in some cutaneous diseases.

Columba is the root of the *Cocculus palmatus*, a native of the forests on the east coast of Africa, whence it is sent to Ceylon, and thence to Europe. It occurs in the form of transverse sections, the bark of which is thick and easily separable: the woody portion is spongy, of a yellow colour, and when old much perforated by worms. The odour is faintly aromatic, the taste bitter and slightly acrid. It contains much starch, a yellow azotised matter, a yellow bitter principle, traces of a volatile oil, woody fibre, salts (chiefly of lime and potassa), oxide of iron, and silex. The active principle is *Columbine*, which may be obtained either by alcohol or æther. Columba is much used in medicine. Other roots are often fraudulently substituted for it; and slices of Bryony root are often employed to adulterate it.

COCHINEAL is extremely rich in the finest red colouring matter, and has been long employed in scarlet dyeing, and in the manufacture of carmine. It consists of a colouring matter, a peculiar animal matter, a fatty substance, and several salts. The chief use of cochineal is the dyeing of scarlet. The fine colour which it yields is converted to this tint by means of chloride or muriate of tin.

The insect which constitutes cochineal feeds chiefly upon *Cactus cochenillifera* and *C. opuntia*. The female insect only is collected. Several varieties are distinguished in commerce, and have different degrees of value attached to them, dependent chiefly upon the different methods employed to kill and dry the insects. When dried, they resemble small grains, scarcely so large as a pepper-corn, ovate, convex above, plane below, transversely furrowed, externally blackish brown, but as if dusted with a white powder, light, friable, the internal substance consisting of extremely small grains, obscurely purple, but when reduced to powder of a rich purple. They are inodorous, but with a bitter sweet acrid taste. They impart to water or alcohol by digestion an intensely red colour.

Cochineal has hitherto been employed mostly as a colouring material, either of tinctures, or of other things, the nature of which it is wished to disguise: but it is also used to a small extent in medicine.

Previous to the revolt of the Spanish American provinces, almost all the trade in cochineal with the different markets of Europe was carried on through Spain, and chiefly through Cadiz; but since that event the markets of consumption are supplied with cochineal either direct from the places of production, or from neighbouring stations, to which the article has found its way in the natural course of commerce. Representing a considerable value in a small bulk, cochineal is frequently used, with great convenience to merchants, as a medium for making remittances, and hence the comparatively circuitous route by which the greater part of it reaches the places of ultimate consumption. The quantity of cochineal imported into Great Britain in 1848 was 18,380 cwt; of which Honduras yielded 9139 cwt., and Mexico 6054 cwt.

COCK, or STOP-COCK. The stop-cocks in most common use consist of a short tube of brass, intersected by a nearly cylindrical plug, capable of being turned on its axis at pleasure, and so perforated or cut that, while in one position it completely prevents the passage of fluid through the pipe, it may be so turned as to permit the fluid to pass through it, and consequently to flow through the pipe. The kind of cock usually employed, under the name of a *tap*, for drawing off the contents of barrels, usually terminates in a curved *nose*, or spout, from which the liquor may be conveniently received in a jug or other open vessel; but, where it is desired to transfer the liquor from the cask immediately to bottles, the nose is prolonged into a long slender tube, which will enter the neck of a bottle, and obviate the necessity for a funnel. Other cocks are adapted for insertion in metallic cisterns or boilers, and fitted with a flange to bear against the outer face of the cistern, and a nut, wormed on to the portion of the tube of the cock which passes into the cistern, by which they may be screwed up firmly. Others again are adapted for soldering to the end of a leaden pipe, such as the service-pipe for laying water on to a house. Some stop-cocks, again, have no nose or spout, but are made alike at each end, for the purpose of being soldered between two lengths of leaden pipe.

In some cocks the plug is so contrived as either to contain a piece of cork, which may be turned so as to close the pipe, or to revolve within a hollow cylinder of cork, with arrangements for opening or closing a passage through it at pleasure. In others the principle of the revolving plug is entirely departed from, and the pipe is closed by means of a flat disc of metal, covered with a leather washer, and screwed up firmly against the end of the pipe, or by a conical or globular valve similarly applied. In such cocks caoutchouc forms an excellent substitute for leather. Another ingenious class of cocks comprises those furnished with contrivances for admitting air to a barrel as fast as the liquor is drawn off, and thereby superseding the use of a vent-peg. Another class are furnished with apparatus for *locking* the cock.

Cocks are most commonly made of *tap-metal*, a peculiar alloy of inferior brass, or rather copper saturated with lead. Fine brass is sometimes used; as also a white alloy made to resist the action of vinegar and other corrosive liquors. For such liquors, however, cocks of porcelain or stoneware are to be preferred. Even wood is occasionally employed; and attempts have been made to manufacture cocks of cast-iron.

The *four-way cock* consists of a plug perforated with two distinct passages, and mounted in a barrel into which four separate pipes or channels open. Its object is to connect the four passages with each other in alternate couples, either by a continuous revolution upon its axis, or by an alternating motion through one-fourth part of a revolution; and it has frequently been applied to steam engines as a means of alternately admitting steam to and allowing it to escape from each end of the engine-cylinder.

COCOA AND CHOCOLATE. *Cocoa* is the more familiar name of the article, the proper name of which is *cacao*; just a reversal of the vowels. It is the cotyledon of the seeds of the cacao plant, which is extensively cultivated in many tropical countries. The Mexicans call the tree *chocolalt*, and hence our name for the seed in a prepared state. The capsules of the fruit each contain about twenty-five seeds. The quality varies greatly; and the Mexicans are accustomed, to improve the flavour of the inferior sorts, to bury them in the earth in heaps, and allow them to ferment for nearly a month. The kinds produced in different countries vary much in the quantity of the oil or butter of cacao which they contain; a product to which much of the nutritious quality is due.

The simplest and best form of using cocoa is that of *cocoa-nibs*, consisting of the seeds roughly crushed. *Flake cocoa* is merely the seeds crushed between rollers. Common cocoa is usually the seeds pressed into cakes, or reduced to a paste.

Chocolate is cocoa brought to a further state of preparation. The seeds or beans, after being carefully picked, are gently roasted in an iron cylinder; and when the aroma begins to be well developed, they are turned out, cooled, and sifted. They are then mixed into a paste, and put into moulds, and when dry they form the ordinary chocolate of the shops, especially in England; but on the continent the chocolate is more frequently sold in a flavoured state, having had vanilla, cloves, cinnamon, almonds, starch, or sugar mixed with it. Lard, sago, and red lead are said to be used in the compounding of some of the cheap kinds of chocolate. The various 'patent' chocolates presented to our notice in the shops, are simply various modes of preparing the cocoa seeds.

The imports of cocoa are now becoming large. In 1848 they amounted to :—

British colonial cocoa	2,602,309 lbs.
Foreign	3,848,677
Hucks and shells	1,208,282
Chocolate and cocoa paste ..	13,016
	7,672,284

COCOA NUT. The cocoa-nut tree is found all over the tropical parts of the world, especially in the vicinity of the sea, growing within reach of salt water, and establishing itself upon reefs and sand-banks as soon as they emerge from the ocean. Its great importance to man has caused it to be cultivated wherever the climate is favourable to its growth; the whole Brazilian coast from the river San Francisco to the bar of Mamanguape, a distance of 280 miles, is, with few breaks, thus occupied; and it was estimated that in the year 1813 no fewer than 10,000,000 trees were growing on the south-west coast of Ceylon. The cocoa-nut palm rises like a slender column to from 60 to 90 feet in height.

In hot countries the uses to which the cocoa-nut tree is applicable are innumerable. The roots are chewed in place of the areca-nut; gutters, drains, and the posts of huts are formed from the trunk; the young buds are a delicate vegetable; shade is furnished by the leaves when growing, and after separation from the tree their large size and hard texture render them invaluable as thatch for cottages; they are, moreover, manufactured into baskets, buckets, lanterns, articles of head-dress, and even books, upon which writing is traced with an iron stylus. Their ashes yield potash in abundance; their midrib forms oars; and brushes are formed by bruising the end of a leaf with a portion of the midrib adhering to it. From the juice of the stem, a kind of palm wine, and subsequently an ardent spirit, are prepared; the farinaceous matter contained in the stem is a good substitute for sago; and a coarse dark coloured sugar, called jagghery, is obtained from inspissating the sap. This jagghery, mixed with lime, forms a powerful cement, which resists moisture, endures great solar heat, and will take a fine polish. The ripe fruit is a wholesome food, and the milk it contains, a grateful cooling beverage; indeed these together constitute the principal sustenance of the poorer Indians in many countries. The fibrous bark is used to polish furniture, as brushes, and to form a valuable elastic cordage called *coir;* the fibrous matter of the husk is also employed to stuff mattresses, and a manufacture of it into cordage, mats, sacking, &c., has lately sprung up in Great Britain. The shell is manufactured into drinking-vessels and vessels of measure; and, finally, the albumen, or white solid matter contained within the shell, yields by pressure or decoction an excellent oil; pressure is the method usually employed. This oil is not only employed for burning, but in the manufacture of torches, and in the composition of pharmaceutical preparations; and mixed with dammer (the resin of *Shorea robusta*) it forms the substance used in India for covering the seams of boats and ships.

Cocoa-nuts are brought to Europe as wedges to set fast the casks and other round packages in the cargo of vessels; their freight therefore costs nothing.

It is a curious circumstance that in commerce there are two kinds of *Cocoa-Oil* or *Oil of Cocoa*, entirely different in origin. The Cacao or cocoa seeds, described in the last article, yield a butter or solid oil which is usefully employed in making candles, soaps, and pomatums—chiefly in France. But that substance which is quoted in our market-lists as *Cocoa-nut Oil* is produced from the cocoa-nut, now under notice. So much has this substance now come into demand, that no less than 64,451 cwts. were imported in 1849.

CODEIA, an alkali discovered by Robiquet in opium, is a bitter, alkaline, crystalline substance, used to a small extent in medicine.

COFFEE. The *Coffee-Tree* or *Coffea Arabica* is an evergreen shrub, with oblong pulpy berries, which are at first of a bright red, but afterwards become purple. It is stated by Niebuhr to have been brought from Abyssinia to Yemen by the Arabs, from a country similar to their own plains and mountains. By that people it has for ages been cultivated in the hilly range of Jabal, in a healthy temperate climate, watered by frequent rains, and abounding in wells and water-tanks. A combination of circumstances seems to favour the cultivation of coffee in Arabia, which can hardly be attained elsewhere. Frequent rains, and a pure and cloudless sky causing an almost uninterrupted flood of light, communicate an excessive stimulus to all the functions of vegetation, and are causes of the perfect elaboration of those delicate principles on which the aroma of the coffee is dependent.

The seed consists of much horny albumen and a peculiar principle or alkaloid, termed *cafeine*, which is identical with the active principle of tea, *theine*, as well as with *paraguaine*, the alkaloid of the Paraguay Tea. The seed is used in a raw state in medicine; but when roasted, it forms the well-known coffee of commerce. The coffee-plant begins to produce fruit when two or two and a half years old; but the quality of the seeds from young stems is not so good as that from stems four or five years old. The size and colour of the bean (as the inner part of the seed is called) vary considerably, those from the West Indies being larger than those from the East.

Much more depends upon the manner of roasting and making the coffee than upon the quality of the bean. The superiority of French coffee, in the preparation of which little or no Mocha coffee is used, proves this position. The taste of raw coffee is somewhat sweetish; but the application of heat in the process of roasting produces important changes. The bean increases to nearly twice the original size, while it loses about a third of its weight: a powerful and agreeable odour is evolved, and a large quantity of empyreumatic oil, which appears in small drops on the surface, is formed along with a bitter principle, probably by an alteration in the cafeine and of the saccharine matter. The roasting should take place in a close revolving iron cylinder, over a clear but moderate fire, and should not be carried too far: when the beans have acquired a light chestnut colour, the roasting should be discontinued. The beans are then to be cooled quickly by being tossed up into the air, and the grinding, or rather rough pounding, should be performed in a covered mortar or mill. The drink should be prepared from it as soon as possible, by infusion, which is preferable, unless some apparatus be employed by which a kind of decoction is made in a close vessel. About half an ounce of coffee powder should be used for every eight ounces (half a pint) of water. In Britain the roasting is generally carried too far; and the subsequent parts of the process, instead of being performed immediately, are often postponed for days or even weeks, by which the aroma is dissipated: when made, the liquid is generally deficient in strength and clearness. The employment of white of egg or fish-skin to clarify is decidedly objectionable: clearness is thus purchased, but at the expense of the strength.

It was an endeavour to establish an improved mode of roasting coffee that led to the death of Mr. Dakin, of St. Paul's Churchyard, in 1848. His plan consisted in placing the coffee in a cylinder lined with silver, and in enclosing this cylinder within a cellular steam oven, or cylinder, patented by other parties. The heat attained within the oven was very great, and the metal of the oven was not sound enough to resist its action: an explosion ensued, with a fatal result. The silver or silvered cylinder was an intended means of retaining the fine qualities of the coffee, without acquiring any defective qualities during the roasting.

The addition of milk (which should always be hot) and of sugar heighten the nourishing qualities of coffee, and in the morning render it a more substantial article for breakfast. When taken after dinner to promote digestion, it should be without milk, and, where the palate can be reconciled to it, without sugar.

The coffee-trade has been wholly created since the beginning of the eighteenth century. Nearly all the coffee which now comes to Europe is the produce of trees propagated from a single plant, which, having been raised from seed procured from Mocha in Arabia, by Van Hoorn, governor of Batavia, was sent by him to the Botanical Garden at Amsterdam, and the progeny of which was, in the year 1718, twenty years after its reception from Java, sent to Surinam.

The coffee imported in 1849 amounted to the following quantities:—

British	...	...	40,334,630 lbs.
Foreign	...	...	22,985,876 lbs.
			63,320,506 lbs.

Of this quantity nearly 37,000,000 lbs. were brought from Ceylon alone.

The use of chicory in coffee has already been adverted to. [CHICORY.]

COFFEE APPARATUS. Considerable ingenuity has been displayed in devising apparatus for preparing coffee for the table. The ordinary coffee pot is the plainest and simplest of all; there is no contrivance for filtering the coffee. In Dresden and other parts of Germany, a thick piece of flannel or some other woven material, is laid in a funnel; the ground coffee is placed on the flannel; and the boiling water filters through the coffee, the flannel. and the funnel, to a vessel below—carrying with it the flavour of the coffee without the grounds or sediment.

Platow's Automaton Coffee Pot has for its object to make coffee in less time and in a better manner than by the ordinary method. The machine consists of of two parts. There is at the top a glass vase which screws off and on by means of wooden handles, and is furnished with a long narrow straight tube, resembling the pipe of a common funnel, and reaching nearly to the bottom of a metallic urn placed beneath the vase. Boiling water is poured into the vase in quantity sufficient for the coffee to be made; and this is allowed to descend into the urn. The ground coffee is then placed within the vase, on a small perforated silver plate. A lamp containing spirit or naphtha is placed beneath the urn; and in a short time the peculiar action of the apparatus developes itself. The steam formed on the surface of the water in the urn forces, by its elasticity, the water up the tube into the glass vase; where it acts upon the coffee in the usual way for extracting the qualities of the berry. When the coffee is so far prepared and is required to be *fined*, the lamp is removed, the formation of steam ceases, a partial vacuum is formed in the urn, and the external atmosphere, pressing on the open vase, presses or strains the coffee, first through the grounds and then through the perforated silver plate; so that it trickles into the urn in the state of a pure bright decoction. It is thus seen that the liquid makes two descents and one ascent between the vase and the urn, during the process. In a cheaper form of the apparatus, a common fire or a lamp is used instead of a spirit lamp.

A coffee pot of rather complicated structure was patented by Mr. Andrews of Wolverhampton in 1842. This coffee-pot had no less an adjunct than a small forcing-pump, placed near the handle. The boiling water was poured in the forcing-pump, while the ground coffee was put in a perforated vessel in the middle of the coffee-pot; and the hot water, being forced by the pump, was made to saturate the ground coffee in a way which (we presume) was supposed to produce a result adequate to the costliness of the apparatus.

Waller's Coffee Pot, patented in 1847, differs in many particulars from all the others. A horizontal partition, perforated near the centre with fine holes, divides the vessel into two equal chambers; an open pipe leads nearly from the top of the upper chamber to near the bottom of the lower chamber; and another pipe leads from the perforations some way down the lower chamber, with a tap or cock which can be worked by a handle protruding through the side of the coffee-pot. The requisite quantity of water, either hot or cold, is poured into the upper chamber, and allowed to flow through the perforations and small pipe into the lower chamber; the ground coffee is placed on the perforated plate; the spout is closed with a cork or plug; and the vessel is placed on the fire. As the water becomes heated, the steam generated has no outlet upwards or sideways, and it therefore presses on the water, and forces it up the long pipe, whence it falls into the upper chamber, upon the ground coffee. When all the water is thus forced up, the coffee-pot is removed from the fire, the vacuum in the lower chamber is condensed, the plug is removed from the spout, the top of the short pipe is opened, and the water trickles through the ground coffee and through the perforations into the lower vessel, imbibing all the soluble and aromatic properties of the coffee as it descends.

COFFERDAM, called by the French a *batardeau*, is a wooden inclosure formed in a river, in order to obtain a firm and dry foundation for the piers of a bridge. It usually consists of a double wall of piles, with intervening space between the inner and outer wall filled with clay or chalk rammed down hard. This done, the water is pumped out from the interior of the cofferdam.

COHESION means the adherence or coherence of particles of matter, by which they form collective masses, requiring the application of more or less force to separate the parts. The gaseous, fluid, and solid states of matter show the most sensible effects of the variations produced by the action of heat in the forces existing between the particles of bodies. In the first state, the particles absolutely repel one another; in the second, a repulsive force is almost exactly counterbalanced by an attractive force, so that there results only that weak degree of cohesion which exists in fluids; while, in the third, the particles absolutely attract each other. Again, two plates of a solid material may be pressed together till the particles at their nearest surfaces are brought close enough to attract one another, so that the plates will remain in cohesion even in a vacuum; and they may be hammered together till the cohesion is as strong as if they had been naturally united. In the force of cohesion we have therefore indications of a real physical attraction: and it follows that there must exist in the intervals between the particles of bodies a repulsive power, having its sphere of action interior to that of the cohesive force; from which we are led to conclude that the particles of bodies really act on one another at a distance.

A few practical considerations connected with cohesive forces, in relation to mechanism and manufactures, are treated of under Strength of Materials.

COINS AND COINING. The production of coins, as a branch of manufacture, is briefly described under Mint.

COIRE, consists of the fibres of the cocoa-nut. The rind of the nut is soaked in water for several months, then beaten upon a stone with a piece of heavy wood, and afterwards rubbed with the hand until the intermediate substance is completely separated from the fibrous portion. The rind of forty average nuts supplies about six pounds' weight of the fibre. This fibre constitutes the coire, which is then ready for use in the same way as hemp or other fibrous materials, for cordage, matting, canvas, &c. Besides the actual weaving or plaiting of this material into textile fabrics of a coarse kind, it is used as a stuffing for mattresses, pillows, and cushions. The availability of coire for such a purpose seems to depend upon these qualities:—that the coire is very indestructible; that it does not harbour vermin, as horse hair would in a warm climate; and that it is free from offensive smell.

COKE is coal divested of its gaseous and more volatile constituents by partial combustion in close chambers, or in heaps from which the free access of air is excluded. The simplest mode of coking coal, which is still occasionally followed, is to lay the coal in large flattened heaps, often containing thirty or forty tons each, in the open air; and to cover it with ashes and earth to confine the heat, so that the mass of coal may be slowly burnt in a smothered manner: men being employed during the process to renew the covering wherever the fire may begin to burn too fiercely. But the best mode of making coke is by means of ovens. These are of different forms; but in principle they consist of an inclosed chamber, in which the coal is burned without access of air: the volatile ingredients are driven off, but the carbon remains. Coke is also made, in the process of making gas, in all gas-works: the coal which is put into the cylinders to make the gas being removed as coke after the volatile matter has been carried off to the gasometer. Coke is much preferable to coal where pure fuel is required in many smelting operations, and where smoke is wished to be avoided. An immense quantity is now used for locomotives; and the principal railway companies have established coke-ovens at their depôts. From a given quantity of coal, the produce of coke is about 20 per cent. less in respect to weight, but 20 per cent. more in respect to bulk.

There has recently been established a company at Alloa, for supplying coke to the railway companies of Scotland. Coke ovens have been built at a spot which lies near the Forth, and also near the Alloa branch of the Scottish Midland Railway; so that there are great facilities both for receiving coal and sending out coke.

Mr. Church's method of making coke, introduced in 1846, has many peculiarities. The coke oven is much more complicated than those usually made, and the process altogether more carefully conducted. The coal is thrown into the oven so as to form a layer about two feet thick over the whole area. A slight depression is made in the middle of the surface of the layer; and in this depression is thrown a little burning coal. All apertures are then closed, except a few for admitting air for combustion, and these are gradually more and more closed as the coking advances. When the cessation of flame shows that the coal is wholly converted into coke, the last aperture is closed. In ordinary coke-making, the coke is cooled by cold water being applied to it; but by Mr. Church's method, two air passages are opened, which allow a stream of cold air to enter a series of passages which run under and around the oven, without communicating with the interior; these passages end in a chimney or flue; so that the air cools the oven as it passes, becomes itself heated, and finally escapes. Not until the oven and the contents are thoroughly cold is the coke removed. The professed object of this method (which, regarded in a scientific point of view is much more complete than the ordinary method) is to produce coke which shall be purer, denser, harder, of more powerful heating quality, and more abundant in quantity, than was before producible from a given amount of coal. Of course a long and strict trial could alone test the existence of these superior qualities.

Mr. Fisher patented a new form of coke-oven in 1849, intended to produce a better ingress and egress of air to the burning mass beneath the coke retorts, than in the ordinary construction.

It has been recently discovered, that although coke is apparently a loose spongy substance, the particles of which it is formed are intensely hard—so hard indeed as to cut glass like a diamond, which no other mineral will effect so well. This is deemed a striking confirmation of the well known chemical fact, that the diamond is nothing more than pure carbon in a crystalline state. It is expected that coke, carefully prepared for the purpose, will gradually come into use as a substitute for the diamond in the ordinary cutting of plate and window glass. Mr. Nasmyth stated at the Swansea meeting of the British Association, that the eminent firm of Messrs. Chance at Birmingham, by whom all the glass for the Crystal Palace has been since made, looked forward to a saving of 400*l.* a year, in respect to this apparently simple discovery.

COLBERT, JEAN BAPTISTE, is worthy of a meed of admiration from all who advocate the advancement of manufactures and commerce. Louis XIV. appointed Colbert contrôleur-général des finances; and Colbert's most strenuous and effective efforts were directed to the encouragement of commerce and manufactures. He succeeded in giving a great impulse to French industry; he roused and directed the national mind towards a new and useful exercise of its faculties. Woollens, silks, glass, pottery, leather, and iron manufactures were either created by him, or greatly enlarged and improved. He founded Quebec and Cayenne, made new settlements in India and on the coast of Africa, and favoured the colonies of Martinique and St. Domingo. He caused the first statistical tables of the population to be made out, and advanced the interests of his country, in industry and commerce, in many ways. Colbert was born in 1619, and died in 1683.

CO'LCHICUM, or *Meadow Saffron*, is a plant with a solid rootstock or cormus, found wild in various parts of Europe and in Great Britain, forming a gay carpet in the autumn in the fields, where its lively purple crocus-like flowers spring up. Its corms and its seeds abound in an acrid, stimulating, deleterious principle, which has been carefully examined by modern chemists, and forms an important plant in the Materia Medica, large quantities of both corms and seeds being annually consumed in the manufacture of *Eau Médicinale*, and other medicinal preparations.

COLLISION. When a body in motion strikes another, whether at rest or in movement, the particles of the first body, at the place of contact, have their forward motions retarded, in consequence of which the particles immediately behind approach closer to those in front than they were before the impact, and thus a condensation takes place. This condensation gives rise to an exertion of the force of elasticity, which acts against the succeeding particles, retarding the motions of these last and giving rise to a new condensation and a new exertion of elasticity against the next succeeding particles; and so on. The like actions must be understood to take place in the body struck; and these actions continue in both bodies till the bodies have attained the state of greatest compression, when, for a moment, both may be conceived to move with a common velocity. After this, the force of elasticity overcoming the force of compression, the particles of both bodies gradually return to a permanent state, which, if the elasticity were perfect, would be the same as that in which they were before the impact, the force of restitution thus causing the bodies to separate as if repelled from each other. A certain interval of time elapses between the instants of first contact and separation, but this is so short as to be scarcely sensible.

If the bodies have different degrees of hardness, an indentation may take place in that which is the least hard, the other penetrating to a certain distance in it. When the bodies are soft, like balls of wet clay, the change of figure produced by collision is manifest. When the hardness is very great, a vast resistance arising from friction will be overcome by the percussion arising from the descent of a comparatively small rammer. It has been observed that a sledge-hammer, in driving hard pegs, produces an effect equivalent to the pressure of 70 tons. It is from this circumstance that collision or percussion is a very valuable mode of applying force, in many of the manufacturing arts connected with machinery.

COLOGNE. This important city has the manufactures and commerce belonging to a sort of metropolis, rather than one distinguishing manufacture. The manufactures are cotton yarns, cotton goods, hosiery, woollens, silks, velvets, tobacco, brandy and spirits, Eau de Cologne, of which above a million bottles are annually exported, &c. Being a free port and having communication by railway with Belgium and various parts of Germany, Cologne has an important transit trade in home and foreign produce. In the vicinity of the city are several coal-mines, and abundance of a particularly fine sort of porcelain-earth and potter's clay. Steamers ply regularly between Cologne and the towns along the Rhine.

COLONIES. The British Colonies exert a most important influence on our National Manufactures. So varied are the climate and productions of those colonies, scattered as they are in every part of the world, that the talent of our manufacturers is repeatedly brought into play to supply the every-day wants of the colonists: especially as it is the policy of England—wise or unwise—to confine her colonial trade pretty nearly to her own manufacturers, merchants, and ship-owners.

In a parliamentary paper published in 1850 the whole of the British Colonies and dependencies, including British India, are placed under 48 headings; and the value of all the British and Irish produce and manufactures, exported to those 48 possessions in the year 1849, is stated. These exports are arranged under 48 headings, according to the kinds of goods exported. Without entering into this degree of minuteness, it may yet be interesting to give the total values to each of the colonies, which we do as follow:—

Colony.	Exports.
Heligoland	357*l.*
Channel Islands	634,125
Gibraltar	533,481
Malta	387,744

It is no less interesting to see which among our manufactures are exported in greatest value to these numerous possessions. Cottons take the lead; in their various forms of piece-goods, hosiery, lace, small wares, twist, and yarn, their value is no less than 7,264,469*l.* Iron, steel, and machinery, amount in value to 1,056,901*l.* All other metal goods (gold, silver, tin, pewter, brass, and copper) give an aggregate of 1,374,316*l.* Woollen and worsted goods amount to 1,275,833*l.* Linen and hempen goods, 710,951*l.* Glass and earthenware. 291,652*l.* Apparel, slops, haberdashery, and hats, 1,281,927*l.* Leather and harness, 349,937*l.* Beer and ale, 294,991*l.* Soap and candles, 202,077*l.* Books and stationery, 309,422*l.*—Out of the sixteen millions sterling, about eleven millions relate to the materials for dress.

The imports from the Colonies to Great Britain consist chiefly in the raw materials of manufactures, and vegetable substances used for food. Their value is not given with the same degree of minuteness in the government tables; but they are less in value than the exports.

Canada, Ceylon, the Cape of Good Hope, and several other of these colonies, will be represented at the Industrial Exhibition.

COLOURS. The word Colour is used in many different ways. Besides its original meaning, in relation to the tints of rays of light, it has gradually come to be applied to the substances by which those tints are imitated.

Painter's Colours, for house-painting and similar purposes, are mostly prepared from mineral substances (white lead, red lead, umber, ochre, &c.) ground up with linseed oil and turpentine to the state of a thick liquid. It would, perhaps, scarcely be supposed that 'Painters' Colours' appear in the Board of Trade tables, as an article of export to the value of about 170,000*l.* annually.

The oil colours for artists are more carefully prepared than those for house painting. They used to be sold tied up in small bladders; but an ingenious and more convenient arrangement is now adopted. Mr. Winsor's envelopes for colours, patented in 1840, consist of small metal or glass tubes, open at both ends, and provided with elastic pistons or plugs of cork or some similar material. The piston has a worm or nut in its centre, which corresponds to a screw attached to a handle rather larger than the tube. The open ends of the tube are covered with small metallic plates having holes in their centres. When the colour is placed in the tube, the arrangement of the apparatus is such as to keep the air from acting on it; and when any is required to be used, the screw is turned round, the piston is pressed down and a little colour exudes from the lower end. Mr. Rand's Collapsible Colour-tubes, so useful to artists, were the subject of a later patent in 1842; the objects of which were, to introduce a mode of punching out by dies the thin pieces of tin of which the tubes are made; and to make a screw cap at the mouth of the tube, to prevent leakage. These little tubes, by a gentle squeeze, are made to yield the colour at one end just in sufficient quantity for use.

Water-Colours for artists include both vegetable and animal as well as mineral substances, and are prepared with very great care.

Mr. Smith of Blackford has lately communicated to the Royal Scottish Society of Arts, a paper showing that when chromate of lead is mixed with muriate of ammonia, and subjected to the action of heat, a substance is obtained of a different colour from either of the matters used. If the proportions of the substances be varied, and different degrees of heat applied, distinct colours and tints will be the result. Thus, when five parts of chromate of lead, and one part of muriate of ammonia, are heated to redness in a crucible, a red colour is obtained; a blue colour is formed by heating 10 parts of muriate of ammonia, and 1 part of chromate of lead to ebullition; and a green is produced when the last mixture is heated nearly to redness. By employing various proportions of the substances, and different degrees of heat, a great variety of tints are formed—scarlets, oranges, browns, blues, purples, greens, yellows, and others. It is conceived that these properties may lead to useful applications in the arts.

COLU'MBIUM, a metal discovered in 1801 by Mr. Hatchett in a ferruginous mineral from North America, is a black powder which by the burnisher acquires the colour and lustre of iron. It is nearly insoluble in acids and in chlorine. When heated in the air, it is oxidised, and converted into columbic acid. Its combinations with other bodies are very little used, or even known.

COLUMBUS. This truly great man exerted such immense influence on the industry and commerce of the last three centuries by his discoveries in America, that it is desirable here to note down the extent and dates of his researches. Born at Genoa in or about 1445, he acquired a taste for a maritime life; and towards the close of the century he conceived the idea of crossing the Atlantic, and reaching Asia on the opposite side from that which it had already presented to European travellers: the intervening Continent of America being then unknown. After many difficulties Ferdinand and Isabella of Spain authorized an Expedition by him in 1492.

On Friday, August 3, 1492, Columbus, as admiral of the seas and lands which he expected to discover, set sail from the bar of Saltes, near Palos, with three vessels and 120 men, who were full of doubts and fears, and were partly pressed into the service. With great difficulty he succeeded in inducing his crew to persevere through a tedious voyage, till on October 11, 1492, the manifestations of land were such as to convince the most dejected. Accordingly, after the evening prayer, Columbus ordered a careful look out, and himself remained on the high stern of his vessel from ten o'clock, when he had observed glimmerings of light, as he supposed on shore, till two in the morning, when the foremost vessel fired a gun as a signal of land having been discovered. Not an eye was closed that night, and on October 12, with tears of joy, after fervid thanksgivings, Columbus kissed the earth on which he landed, and with great solemnity planted the cross in the new world, at Guanahani, or San Salvador, one of the Gucayos, Lucayan, or Bahama Islands. Those who had lately been most in despair were now the most extravagant in their joy.

On the 24th Columbus set out in quest of gold and Cipango (Japan). After discovering Concepcion, Exuma, and Isla Larga, Cuba broke upon him like an elysium; he no longer doubted that this beautiful land was the real Cipango. When this delusion was over, he fancied Cuba, which to the day of his death he took for part of the main land of India, to be not far from Mango and Cathay. He next took Hayti or Santo Domingo for the ancient Ophir, the source of the riches of Solomon, but he gave it the Latin diminutive of Hispaniola, from its resembling the fairest tracts of Spain. Leaving here the germ of a future colony, he set sail homeward January 4, 1493. After weathering a dreadful storm, he at last landed triumphantly at Palos, March 15, 1493. He proceeded to Barcelona, where Ferdinand and Isabella received him seated in state, rose as he approached, raised him as he kneeled to kiss their hands, and ordered him to be seated in their presence.

On September 25, 1493, Columbus left Cadiz on a second expedition, with seventeen ships and 1500 men. He discovered the Caribbee Islands, Puerto Rico, and Jamaica; and after repeated mutinies of his colonists, and great hardships, he returned against the trade-winds to Cadiz, June 11, 1496. Having dispelled various calumnies that had been accumulated upon him, Columbus embarked on May 30, 1498, at San Lucar de Barrameda, on a third expedition, with only six vessels. In this voyage he discovered Trinidad, the mouths of the Orinoco, the coast of Paria, and the Margarita and Cubagua Islands. On August 14 he bore away for Hispaniola to recruit his health. While here the intrigues of his enemies induced Ferdinand, in July 1500, to despatch Francisco Bovadilla to supersede Columbus, and bring him back in chains. Vallejo, the officer who had him in charge, would have taken his chains off; but Columbus proudly refused. The general burst of indignation at Cadiz, which was echoed throughout Spain, on the arrival of Columbus in fetters, compelled Ferdinand himself to disclaim all knowledge of the shameful transaction. With restricted powers and a broken frame, but with his ever-soaring and irrepressible enthusiasm, Columbus sailed from Cadiz again on May 9, 1502, with four caravels and 150 men, in search of a passage to the East Indies near the Isthmus of Darien, which should supersede that of Vasco de Gama. The mutiny of his crew compelled him to return to Hispaniola after coasting the Mosquito Coast, Costa Rica, and Veragua to the point called El Retrete. He reached Santo Domingo August 13, 1503. Sailing homewards on September 12, he anchored his tempest-tossed and shattered bark at San Lucar on November 7, 1504. From San Lucar he proceeded to Sevilla, where he soon after received the news of the death of his patroness Isabella. He was detained by illness till the spring of 1505, when he arrived at Segovia, to have only another courtly denial of his redress, and to linger a year longer in neglect, poverty, and pain, till death gave him relief at Valladolid on the 20th of May, 1506.

COLUMN. The column, in architecture, is a shaft of wood, stone, or iron, in the form of a truncated cone, a little swelled from the straight line at about one-third its height from the lower extremity: this swelling is called the éntasis. Columns are of various proportions and kinds: circular on the plan, and rarely polygonal. The Romans had five models of columns, which were called orders;

but the Greeks, from whom the Romans appear to have derived their architecture, only three. The Egyptians used columns, but they were very different in their form and proportions from both the Roman and Greek examples.

It seems not at all improbable, that the admirable construction of the Palace of Industry by Messrs. Fox and Henderson, in which light and graceful columns of iron form so notable a feature, will go far to bring into vogue a new kind of architecture, in which unexpected resources may gradually develope themselves.

COMB-CUTTING. The old method of forming the teeth of combs is by means of a double saw, which consists of two separate fine saws, placed parallel with each other, and adjusted to such a distance from each other as to embrace a tooth of the required fineness between them. These two saws are so arranged that, while one cuts into the comb to the full depth required, the other cuts only about half that depth, and by this contrivance the uniformity of the comb is secured, because, while the deeper saw is completing the first cut, the shallower one is forming the commencement of the second, and when, on the completion of the first cut, the deep saw is put into the second cut to complete it, the shallower one immediately commences a third The cuts thus formed are subsequently enlarged and rendered smoother by means of a very thin wedge-shaped file, which also points the teeth. Though this method of comb-cutting is still practised, a much quicker mode of performing the same operations by means of circular saws and revolving cutters for pointing the teeth has been long in use.

By the above described modes of comb-cutting all the material of the interstices between the teeth is lost or destroyed, but by the operation known as the *parting* of combs such loss or waste of material may be avoided in the manufacture of combs of tortoiseshell, horn, or any tough material. Two combs are by this process, made out of one piece, the teeth of one being cut, by the pressure of chisel-like instruments, out of the interstices of the other.

An American patent was taken out in 1839, by Mr. Ives of Connecticut, for making metallic combs by the following method. A strip of sheet metal is prepared, of a width equal to that of the intended comb, and of a thickness equal to that of the intended teeth. The piece of metal is bent or plaited in a zig-zag manner crosswise: the bends being of such width only as shall adapt them to the forming of a single tooth. The bending is effected by a sort of crimping rollers; and these plaits or bent portions are placed up together, being kept separated by a distance equal to the interval between the teeth of the intended comb. Ribs are soldered to make the back of the comb; and the two surfaces are smoothed or cut away, so as to separate the several plaits, and make each one stand singly as a tooth of the comb.

COMBINATION LAWS. These laws, which were an object of much solicitude to manufacturers and artizans, were repealed in 1824. Till then any combination of any two or more masters, or any two or more workmen, to lower or raise wages, or to increase or diminish the number of hours of work, or quantity of work to be done, was punishable at common law as a misdemeanour; and there were also thirty-five statutes in existence, most of them applying to particular trades, prohibiting combinations of workmen against masters. The act passed in 1824 repealed all the statute and common law against combinations of masters and of workmen, provided a summary mode of conviction, and a punishment not exceeding two months' imprisonment, for violent interference with workmen or masters, and for combinations for violent interference; and it contained a proviso, with regard to combinations for violent interference, that no law in force with regard to them should be altered or affected by the act. But, all the common law against combinations being repealed by the act, this proviso was considered as of no force; and the act also went beyond the intentions of the framers in legalising combinations unattended with violence for the purpose of controlling masters in the mode of carrying on their trades and manufactures, as well as peaceable combinations to procure advance of wages or reduction of hours of work.

Immediately after the passing of this act a number of widely-organised and formidable combinations arose in various trades and manufactures for the purpose of controlling the masters as to the way in which they should conduct their business; and the extent to which the act had repealed the common law being doubtful, and the act having clearly gone beyond the resolutions on which it was grounded in legalising combinations, the act of 1825 was passed, which is the act now in force relative to combinations. It relieved from all prosecution and punishment persons meeting solely to consult upon rate of wages or hours of work, or entering into any agreement, verbal or written, on these points. And it provided a punishment of not more than three months' imprisonment, with or without hard labour, for any one using violence or threats to make a workman leave his hiring, or return work unfinished, or refuse to accept work, or belong to any club, or contribute to any common fund, or pay any fine for not belonging to a club, or contributing to a common fund, or refusing to conform to any rules made for advance of wages or lessening of the hours of work, or regulations of the mode of carrying on any business, and for any one using violence to make any master alter his mode of carrying on his business. By this act therefore, combinations of masters and workmen to settle as to rate of wages and hours of labour are made legal: but the common law remains as it was as to combinations for otherwise controlling masters. This enactment does not necessarily interfere with plans for joint enterprises among workmen. [CO-OPERATIVE SYSTEMS.]

COMBUSTION, a process in which both light and heat are emitted by chemical agency. When a piece of charcoal is ignited and put into oxygen gas, combustion commences and continues with increasing brilliancy until the charcoal disappears, or the oxygen has undergone a change which renders it incapable of further action as a supporter of combustion. This is an example in which a gas (carbonic acid) is the result of the combustion; but in other examples, such as burning iron in oxygen gas, a solid oxide is produced. *Ignition* differs from combustion in this, that the heated body gives out light and heat without undergoing decomposition. In all common cases of combustion, the heat which is generated by it is accompanied by flame, but not necessarily so. Some idea of the difference may be formed by observing the circumstances under which bituminous coal and anthracite burn; the former burns with flame, and the latter with scarcely any.

COMPASS, AZIMUTH. This instrument used by astronomers and by surveyors, is a compass with a telescope, or with plain sights (generally vertical wires) attached to it in such a manner as to be moveable round a vertical axis independently of the needle or of the card to which the needle is affixed. A pointer shows the angle which the position of the telescope, or sights, marks out on the card, that is, the *bearing* of the object towards which the sights are directed. This angle is the true azimuth of the object.

COMPASS, THE MARINER'S. This invaluable instrument is a cylindrical box, generally of brass, in the centre of which is fixed vertically a steel pin terminating in a fine conical point, and on this is accurately balanced a magnetised needle, or a circular card to the underside of which such a needle is attached in the direction of a diameter. In the centre of the needle is usually inserted a piece of agate in the lower part of which is sunk a conical hole to receive the point of the pin; and the needle with the card is supported on that point so as to *traverse* freely in a horizontal position. The rim of the compass-box, or the circumference of the card, is divided into thirty-two equal parts called *points*, which have symmetrical designations on opposite sides of each of the four cardinal points as they are called, namely, the north, the east, the south, and the west. In some compasses the points are subdivided into *quarters* of 11¼ degrees each, and sometimes into single degrees.

When the needle is attached to a card, the north point on the card is directly over the northern extremity or pole of the needle. To insure the horizontality of the compass-card the cylindrical box in which it is enclosed is supported in a hoop at opposite points by pins projecting from it, so as to allow the box to revolve inside the hoop. This hoop is supported in the same manner on pivots, the line of which is at right angles to the first pivots; so that, between the rotation of the compass-box in the hoop and the hoop itself, the former can always find its position of equilibrium, which is the horizontal position. The small oscillations of the apparatus are immediately destroyed by the friction. The apparatus is then said to be supported on gimbles, or gimbals.

The Mariner's Compass still remains, in principle, what it has been for ages; but there have not been wanting attempts to improve it in minor details. Mr. David Napier included in his patent of 1848 a kind of compass-box having an analogous movement to that of his barometer [BAROMETER]. There is ordinary clock-work machinery placed at the bottom of the compass-box. Connected with this are a lever and a pricker, which rise and fall at certain regular intervals of time. Within the compass-box is placed a ruled circular piece of paper containing 24 concentric circles, and a number of radiating lines corresponding to the points of the compass in a compass card. The vertical pricker is made to travel over the surface of the paper from the inner concentric circle to the outer one, and in a line parallel with the keel of the vessel, once in 24 hours. The pricker punctures the paper at certain regular intervals of time; while the paper follows the movements of the magnet and compass card; the consequence of which is that the direction of the ship's course will be indicated by the punctures on the radiating lines, while the hours of the day which correspond to these directions will be marked by the punctures on the concentric circles. A new paper has to be used every day: each paper being a record of one day's proceedings.

The Admiralty have recently bestowed a good deal of attention on the *storm compasses* of Mr. Walker, which are becoming extensively used in the navy. During a storm the ordinary compasses are liable to great derangement by the violent commotion; and Mr. Walker has sought to devise such an adjustment of the apparatus as will bring this evil to a minimum.

COMPASSES. There are many varieties of these useful instruments. The *Common Compasses*, or *Dividers*, are simply two pointed legs on a common pivot, for transferring distances. For drawing a circle the lower end of one of the legs is removed, and its place supplied by a holder for a pencil, or by a steel pen. In the *Hair Compasses*, one of the legs has a part attached to the upper part by a spring, so that by means of a screw a very small motion may be given to the lower end; the instrument is convenient for very accurate dividing, but must be used with care. *Triangular Compasses* have three legs and two pivots, so that the three points of a triangle can be at once transferred; the instrument is useful only in rough work, as it is difficult to handle. *Proportional Compasses* consist of two dividing compasses with a common pivot, which, when open, present vertically opposite angles; consequently, the intervals between the points of one and the other are in the same proportion as the legs of one to the legs of the other. The pivot is a clamping screw, which can be transferred along the interval between the pairs of points; and a scale points out how to adjust the instrument to alter any line, or surface, or solid, in a given proportion. These compasses sometimes have an apparatus for slight adjustment. *Beam Compasses* consist of a cylindrical bar, perpendicular to which, with clamping screws, slide a point and a pencil. The use of it is to describe large circles, or measure large distances, the common compasses being very liable to slip when opened very wide. It is a very safe and sure construction.

A machine used as a substitute for compasses, in describing a curve passing through three or more points nearly in a straight line is made as follows:—An elastic rod of metal is furnished with a rigid bar on which it can be drawn up by screws, so that the rod shall form an arc, the chord of which is a part of the bar. This may be adjusted so as to pass through the given points when the curve is to be traced along the front of the rod. This is sometimes called a Shipwrights' Bow.

COMPOSING MACHINES. In ordinary typography [PRINTING] the types are collected one by one, by the fingers of the compositor, from little cells or compartments, and arranged in the proper order for printing. About ten years ago however two very ingenious attempts were made, by Messrs. Young and Delcambre in one case, and by Captain Rosenberg in the other, to perform this work by the aid of a machine.

Messrs. Young and Delcambre's first composing machine was patented in 1840; but by the year 1842 considerable improvements had been introduced in its mechanism. Considered in its latest form, it does not set up types in a state fit for printing from; but it is intended so to facilitate the process of composition as to enable that to be done by females and children which now requires the services of highly paid men, and to do the work more quickly.

The mechanism for carrying out this intended object may be described as follows. The general appearance of the machine somewhat resembles that of a cottage piano forte, without its case. There is a row of keys which are played upon by the fingers of the compositor, who is seated in front of the machine. There is one key to each letter, stop, numeral, space, &c., required in printing; so that the number of keys must be very considerable. Each key is marked with its particular letter or other type, and each type is placed in a receptacle containing many duplicates of that character. These receptacles are all filled with types by boys; and one compositor can use the types as fast as two boys can supply them. The compositor seats himself in front of the instrument, with the author's MS. placed before him. We will suppose the first word to be *The*. He places his finger on the key marked with a capital T; the key moves an upright steel lever, the upper end of which pushes a type out of its receptacle or channel; this type is a T, which slides down an inclined plane, in a little hollow or groove, until it reaches a sort of spout at the bottom; thence it passes to the justifying-box, where the automatic action of the machine terminates. Here another compositor takes up the type and arranges it in the composing stick, as in ordinary printing. While the T has been thus travelling downwards, the *h* and the *e* have been made to follow, and are treated exactly in the same way; and so on throughout the MS. The number of persons required to work the machine is five; viz. two to distribute the type used in previous printing and to supply the types to the receptacles, one to play the keys, one to work an excentric wheel which forces the arranged types into the justifying-box, and one to justify or place the types in the composing stick. Two of the persons are females, and three boys; and these five are said by the inventor to be able, after six months practice, to compose and distribute 6000 types in an hour; 1,500 per hour being an ordinary compositor's work, including corrections.

It is singular that two machines were in progress for the same object about the same time. Rosenberg's Type Composing Machine was patented in 1841, shortly after the first patent of Messrs. Young and Delcambre. The two machines bear a strong general likeness; but there are sufficient points of difference to mark the ingenuity which has been shewn in each. Rosenberg's Machine is rather more compact of the two, and effects more by automatic means—requiring the aid of fewer persons. In Captain Rosenberg's own statement of the capabilities of his machine, he claims for it the the power of composing 10,800 types in an hour; of requiring only three persons instead of five; and of distributing the type as well as composing it, instead of composing only as in Young and Delcambre's machine.

The compositor, pressing on the keys in succession, forces down the several types from a series of vertical racks in which they had been placed. The types arrange themselves in proper order upon an endless belt or chain, which is constantly passing through the middle of the machine from right to left. The types travel along this endless band till they come to a receiver, where they rank themselves closely side by side until enough are so arranged to form one line of the book to be printed. The compositor is warned by the striking of a little bell that the line is full; and by turning a handle close to him, he removes the finished line from its place, and leaves room for the next line. An assistant compositor then takes up the finished line, in a small apparatus into which it falls, reads it, corrects any mistakes, and places it in the page of type ready for printing. All the *leads* for 'spacing' the type are applied by hand by this assistant compositor. The arrangement of the types in their original receptacles is so peculiar, that the compositor can sometimes compose or bring down four or five types at one time, by pressing four or five keys at once, as a pianoforte player can do. This may be done whenever the letters of a word succeed each other in the order which they follow in the alphabet. For instance, in the word *adopt* each letter has a later alphabetical rank than the one which precedes it; so that if the five corresponding keys be pressed down at one time, the five types will be found ranged in their proper order on the endless band: it is true that they will be unequally distant apart; but they all become pressed together closely at a later stage of the operations. The word *accentuation* is given as an example wherein three pressures on the keys will suffice instead of twelve; thus, *accentu—at—ion*, in which each of the three groups consists of letters which take rank in their proper alphabetical order.

The *Distributing* Machine is quite detached from the *Composing* Machine. When the printing is completed, a line of type is lowered from the galley [PRINTING] into a sort of travelling carriage, by means of a slider with a handle. The distributor reads over the line, and puts his finger successively on a row of keys, each key corresponding to a particular letter; the key is raised by the touch, and he moves the carriage sideways until it is stopped by the key which has been thus raised. The type contained in the carriage is by this movement forced out of the line in which it had previously held a place, and falling down through a recess, it is deposited in a small receptacle. By the time the whole line has been thus distributed, by touching the keys as many times as there are types in the line, all the *a*'s are found in one receptacle, all the *b*'s in another, and so on. By means of a 'feeding-stick,' 200 or 300 of these types of one letter may be lifted up and transferred from the distributing machine to the composing machine, ready to be used over again.

There is considerable mechanical beauty in these two machines, especially Rosenberg's; and the leading printers would certainly by this time have adopted them had the statements of the respective patentees been borne out. It seems however now fully decided that a book cannot be printed so quickly or cheaply by the aid of these machines as by the ordinary means.

CONCAVE and CONVEX. A curve or surface is concave on the side on which straight lines drawn from point to point in it fall between the curve or surface and the spectator; that side is convex on which the curve or surface falls between such lines and the spectator. A surface may be either entirely concave, as the inside of a sphere, or entirely convex, as the outside; or concave in some directions and convex in others, as the surface of a dice box.

CONCENTRIC, means having the same centre; thus concentric circles are those described about the same point.

CONCERTI'NA, a musical instrument recently invented by Professor Wheatstone, the principle of which is explained under the word ACCORDION. One variety is called the Double-Action Concertina, because two springs are given to each note, in order that the same sound may be produced whether the bellows be pressed in or drawn out. The Single Action Concertina has but one spring or tongue for each note, yielding a sound only when the bellows are moved inwards; that is, pressed. There are treble, tenor, and base concertinas, embracing different portions of the musical scale. The concertina is far more complete as an instrument than the accordion.

CONCRETE. This name is given to a very useful kind of cement or rather rough earth, largely used in the foundation of buildings. It usually consists of crushed pebbles, rough sand, and lime. The Palace of Industry affords an example of the useful application of concrete, as a means of preserving wood and iron from damp. The columns and the flooring joists are shielded from the damp soil by layers of concrete.

CONDENSER, is the general name for a vessel employed to facilitate the liquefaction of aqueous or spirituous vapours, by exposing them to the cooling effect of a current of water, which may be either injected immediately upon or among the vapour, or, where it is required to keep the condensing water and the product of condensation distinct, separated from the vapour by a thin partition of metal. In the latter case, copper is the metal most generally employed, on account of the rapidity with which it conducts heat, and the facility with which it may be fashioned into thin sheets adapted for the purpose. Mr. Siemens described before the Society of Arts in 1850 a remarkable condenser, so contrived as to save or render available the heat developed during the process of condensation. [Brewing; Distillation; Steam Engine; Steam Vessel.]

CONDIMENTS are substances taken with food, either to impart flavour or to promote digestion: such as salt, vinegar, lemon-juice, aromatic herbs, oil, butter, sugar, honey, and sauces.

CONE. The following measurements relating to the cone are often useful. The *surface* of a cone is one-half the circumference of its base multiplied by the distance from the vertex to the circumference of the base (called the *slant side*). The *solidity* of a cone is one-third of the product of the area of the base and the perpendicular distance of the vertex from the axis.

CONFECTIONS, called also *Conserves* and *Electuaries*, are formed of fresh, generally succulent, vegetable substances, in a few instances with prepared chalk, as in the aromatic confection, preserved by means of sugar or honey. These were formerly much more numerous than at present.

When astringent substances, such as roses, are to be pounded, this process must be conducted in marble, not iron, mortars. The conserves should be put into several small pots, rather than one large pot, which should be glazed with salt, as in Bristol ware, not lead. They should then be well closed, and kept in a dry cool place. Patent jars, of a very useful kind, are now manufactured for this purpose.

There are more than twenty varieties of confections, whose names find place in books of receipts.

CONGELATION. [Freezing Mixtures.]

CONGLETON. At one period the chief manufactures of Congleton were gloves, and tagged-leather laces called Congleton points; but for nearly a century the silk manufacture has been the principal occupation of the inhabitants of the town. A number of mills for the manufacture of silk (chiefly black silk), for silk throwing, silk spinning, &c., are situated in Congleton and its immediate vicinity. The making of silk ribbons has of late years grown into an important branch of industry, in which females as well as males find employment. In the neighbourhood are several extensive coal mines. The Congleton viaduct of the North Staffordshire Railway, about half a mile from the station, is a fine work of ten arches. It is constructed of blue brick with stone bastions and stone parapet. The arches are 50 feet in span. The height from the bed of the stream to the rails is 114 feet; the length of the viaduct, exclusive of the embankments, is 231 feet.

CONGREVE LIGHTS. [Matches.]

CONGREVE ROCKETS. [Rockets.]

CONIA, is an alkali obtained from hemlock (*Conium maculatum*). It is procured from the seeds or fresh leaves of the plant by distillation with water holding some potash in solution. It has the appearance of a colourless volatile oil, and is lighter than water, its specific gravity being 0.89. Its odour is powerful, diffusible, and repulsive, somewhat like that of hemlock itself. It is intensely acrid to the taste, and is strongly alkaline. By exposure to the air it quickly becomes of a dark colour, and spontaneously decomposes with the evolution of ammonia.

Conia is an awfully-rapid poison; but when greatly diluted it is used in medicine.

CONNAUGHT. This, the north-western province of Ireland, is almost shut out from industrial connection with England. It is very poor, and the potato failure of 1847 rendered it still poorer. There have been lately, however, numerous projects formed for the improvement of this province, and the development of its great resources. Of these the chief is the extension, now in progress, of the

Great Midland Railway from Mullingar by Athlone to Galway. Another is the establishment of a packet station for the conveyance of the mails from that port to Halifax. The Viceroy steam-ship was placed on the station in 1850, but was not of sufficient dimensions to perform the voyage with the requisite speed; and having been wrecked on the return passage from New York to Halifax, has not as yet been replaced. The merchants of Galway are at the present time strenuously endeavouring to have that port selected as a mail-packet station. The improvement of the navigation of the Shannon has given a continuous line of water carriage along the eastern boundary ot the province. It has also been in contemplation to connect the lakes of Galway and Mayo, so as to form a line of navigation from Galway to Killala, through Loughs Corrib, Mask, Carra, Castlebar, Cullin, Conn, and the river Moy to Ballina, a distance of 80 miles, through a district susceptible of immense improvement. To connect these lakes it would require a series of cuts only 17 miles in length.

Perhaps the most useful of the various efforts made for the improvement of Connaught has been the introduction or revival of the culture of flax. The quantity grown in 1847 was 10,866 cwt. and the cultivation of flax crops is since then much increased. The system of farming has been greatly improved in these districts which have passed through the transition attendant on the recent change of proprietary and occupants.

CONSERVE. A conserve differs from a *confection* in having a more definite relation to some particular vegetable substance. All conserves are pasty mixtures of sugar with some recent or fresh vegetable, whether fruit, flowers, or leaves. Their number is considerable.

CONSERVATORY, properly so called, is a building heated by artificial means, having its whole southern part closed by large glazed sashes, which may be opened or shut at pleasure. Its floor is generally of stone, and a part of it is occupied by a stage on which plants in pots can be placed. Plants when in a growing state require an abundant supply of light: a conservatory is ill calculated, on account of its solid roof and sides, for the admission of light, and consequently a conservatory is not suitable for plants in a growing state; but plants when torpid, as in the winter season, require a very moderate supply of light, and this a conservatory is sufficiently calculated to admit.

A house of this kind is best suited for gardens of considerable extent, where a large number of plants is required during the summer for the ornament of the flower garden and shrubbery. Under such circumstances the erection of conservatories is the cheapest, the most efficient, and the most ornamental mode of preserving in a healthy state during winter not only oranges, myrtles, and similar plants, but in general all the species which are natives of countries that, without experiencing severe frost, are cold enough during winter to suspend the vital energies of vegetation.

A most important change has recently been introduced by Mr. Paxton in the principle of construction in conservatories, by the substitution of iron and glass for brickwork. The Duke of Devonshire's magnificent conservatory at Chatsworth, planned by Mr. Paxton, is composed entirely of iron and glass. The length is nearly 300 feet, the width 150, and the height 70. It covers nearly an acre of ground, and has a carriage drive through it. The tubes for the hot water which regulate the temperature are six miles in length. A light but beautiful gallery extends round the upper part of the interior of the building; while around the foundation is a tunnel, which gives access to the stoves and pipes.

The new Palm House in Kew Gardens is another beautiful example of the same kind of construction. It is 362 feet long, 100 feet wide by 66 high at the centre, and 50 feet wide by 30 high at the wings or ends. The curves which the glassy surface is made to assume are exceedingly graceful. A gallery runs round the lofty central portion, which is reached by an elegant iron spiral staircase. The glass employed has had a pale yellowish green tint imparted to it, to temper the heat of the solar rays. The structure is heated from beneath by stoves, the chimney of which, made somewhat ornamental, is at a considerable distance.

That triumph of constructive skill, the Palace of Industry in Hyde Park, was suggested by Mr. Paxton on the strength of the experience which his conservatory-building has afforded him; and Messrs Fox and Henderson have worked out the idea with masterly results. This palace will be described in another part of the present work.

CONSTANTINOPLE. This capital of the once great Turkish Empire is commercial rather than manufacturing. The harbour formed by the strait called the Golden Horn is deep, commodious, well sheltered, and capable of containing above 1000 large ships, which may load and unload alongside the quays. The number of vessels that enter yearly is from 5000 to 6000; and the departures about the same. About 2000 tons of coffee, 1,200,000 lbs. of sugar, 300,000 lbs. of spices, 2000 puncheons of rum, and very large quantities of cheap cottons, are annually imported. Other articles of import are dye-stuffs, woollens, cotton-twist, cutlery, coals, iron, furniture, nails, butter, cheese, flour, paper, glass, watches, jewellery, &c. The exports are wool, silk, opium, otto of roses, wax, hides, bullion, diamonds, goat's hair and skins, valonia, box-wood, mohair, yarn, &c. Steamboats ply regularly to Trieste, Smyrna, Odessa, the Danube, and Trebisond, under the management of an Austrian company; and to Malta, Gibraltar, and Southampton, under the Peninsular and Oriental company.

Among the earliest continental arrivals of products of industry for the Exhibition in Hyde Park, has been a consignment from Constantinople, transmitted at the expence of the Sultan. It comprises both natural products and manufactured specimens, from various parts of Turkey.

CONTENT, or CAPACITY. The content, or quantity of space contained within any given boundary, is calculated by certain rules. The solid content of a *parallelopiped* (or figure like a box) is found by multiplying together the units in the lengths of its three dimensions. Thus, 3 feet of length, $2\frac{1}{2}$ feet of breadth, and 4 feet of height, give $3 \times 2\frac{1}{2} \times 4$, or 30 cubic feet. The solid content of any *cylinder* or *prism* is found by multiplying together the number of square units in the base and the number of linear units in the altitude; and one-third of a similar product is the content of a pyramid or a cone. The content of any irregular solid bounded by planes must be found by dividing it into pyramids.

COOKING APPARATUS. If cookery be raised to the dignity of a chemical art (and there is no good reason why it should not) we ought to regard cooking vessels as chemical apparatus. It is, however, chiefly in the mode of applying and economising heat, that such apparatus calls forth the exercise of ingenuity.

Of the ordinary cooking vessels we need say nothing; their simplicity has rendered them familiar to all; but of the modern cooking stoves and apparatus, many examples evince skilful arrangement.

In the so-called 'bachelor's kettles,' of which Spiller's is a recent specimen, the problem seems to be to determine in how short a space of time, and with how little trouble, can a frugal meal for one person be prepared. Spiller's apparatus consists of a kind of saucepan, with a small opening on one side to admit air, and a flue fixed in the opposite side to let off smoke. A very shallow tea-kettle forms the cover to this saucepan. In the middle of the saucepan is a small iron grating, and on this grating is placed one of those small net-work arrangements of sticks which constitute 'patent firewood' and which are now sold so cheaply at one farthing each. This wood being kindled, and the kettle placed over it, the heat is so confined as to make the water in the kettle boil by the time the wood is consumed. With some of these contrivances a kind of small frying-pan is sold; and by using a larger piece of patent firewood, time is allowed for a small dish of savory cookery after the water has boiled: the kettle being quickly replaced by the pan. There is a certain amount of usefulness in the contrivance, which makes it available for others besides the 'bachelors' whom the patentee seems to have had in his thoughts.

Many varieties of gas cooking-stoves have been introduced, in which gas jets are made to yield heat sufficient for the processes of boiling, stewing, roasting, baking, frying, &c. Among other varieties is Defries' 'Economic Gas Cooking-stove,' which is made to suit either large or small culinary wants. Mr. Boggett's gas stoves, for which a patent was taken out in 1850, comprise many varieties, which differ from each other chiefly in the mode of making the heat practically available. There is one form called the Liverpool Gas stove, in which separate departments are provided for roasting, baking, broiling, frying, boiling, stewing and steaming. For many of these purposes the gas is supplied in a ring of jets. On a recent festive occasion at Exeter, M. Soyer cooked a monster joint of meat by means of this apparatus. The meat weighed 565 lbs., and was cooked in a gas oven in five hours, with an expenditure of about five shillings worth of gas.

The kitchen ranges, and other stoves and grates in which coal or coke is burned, are for the most part contrived both for warming apartments and for cooking; but some are designed especially for cooking. The Cottager's stove, designed by Mr. Grant, and manufactured by Messrs. Bailey of Holborn, consists of a square iron case supported on four legs. Inside this case, and near one end, is a fire-pot, the top of which opens into a flue to carry off the smoke; the rest of the vacant space constitutes an oven; while the top, being flat, is available for many cooking processes. In some of these stoves a boiler is attached to that end which is nearest to the fire.

The cooking apparatus of Messrs. Burbidge and Healy is founded on the plans of heating developed by Mr. Sylvester. There are, as in many other similar kinds of apparatus, a large range, an oven, a boiler, a hot-plate, and various subsidiary parts; but its chief features consist in the economising of fuel, and in lessening the amount of radiation sent into the middle of the room. This radiation is an annoyance to the persons present, and involves a loss of some of the heat produced; and it is unquestionably an improvement, other things being equal, if nearly the whole of the heat produced can be applied to the purposes for which it is primarily intended.

Among the many forms of cooking apparatus, that of Mr. Brown is distinguished by having the whole kitchen range, with its oven boiler, hot-plate, &c., set in a frame-work which may be placed in any sized fire-place, however large, without setting. The throat, or opening to the flue, is formed in the iron-work of the range itself, so as to be at once determinate in shape and size. With this range is used an Automaton Roasting jack, arranged in a singular way. In front of the range is placed a sort of semi-cylindrical oven, with the usual hooks and dripping pans for roasting. A hollow tube projects from the lower part of the oven; and when the oven and range are arranged for cooking, this tube is thrust into an opening beneath the fire-place of the range. While the contents of the oven are exposed to the action of the fire, a current of air is continually drawn through the tube into the oven; and this current sets in rotation a vane-wheel to which the suspended hooks are attached.

Remington's Roasting apparatus, recently introduced, is, as the name imports, adapted to roasting only. The meat is suspended and roasted by a jack. There are concave reflectors above and below, which reflect the heat so as to act on the upper and under surfaces of the meat. The centre of both reflectors is perforated; the fat which drips from the meat passes through the perforation in the lower reflector into a small vessel beneath, and is from time to time poured into another vessel, which is perforated and placed over the perforations in the upper reflector. The inventor hence calls his apparatus not only a roaster, but a 'self-acting baster.'

M. Soyer, whose gastronomic skill has acquired some notoriety, has devised a very pretty and scientific cooking stove, in which spirit is the fuel used. A lamp is so placed as, by its heat, to boil spirit placed in a vessel above; the steam or vapour of this boiling spirit has no outlet, except through a tube which gradually becomes so narrow as to resemble a blow-pipe; this blow-pipe is placed opposite to a second spirit-flame, and the blowpipe wafts such a constant stream of spirit-vapour into this flame as to heat it greatly, and to make it act rapidly on small cooking vessels placed above it. There is a good deal of chemical ingenuity shewn in thus feeding one spirit-flame by vapour derived from another.

COOLER. For cooling wine, wort, &c., the hot liquor is sometimes exposed in shallow wooden vessels, and stirred with fans to keep the liquor in motion, and thus expose fresh surfaces to the air. Sometimes cold spring water is allowed to pass through metal pipes placed in the liquor which is to be cooled. In Spain and Egypt, wine is cooled by placing it in porous earthenware vessels, called by the Spaniards *Alcarrazas:* the vessels are wetted externally, and the consequent evaporation occasions cold within.

A remarkable mode of cooling liquids was introduced in 1848 by Mr. Lillie of Manchester. It depends on centrifugal force. The liquid is placed in a bowl or colander, either pierced with minute holes all round the sides, or having sides made of wire gauze. Through the intervention of a vertical shaft, this bowl is made to rotate rapidly. The water first rises all round the sides, and then rushes out through the perforations or meshes in a multitude of small streams; these streams, coming in contact either with the ordinary atmosphere in an outer vessel, or still more effectively with artificial currents of air, become rapidly cooled.

Professor Smyth, of Edinburgh University, has recently suggested a method of cooling the air of rooms in sultry weather. It depends on the principle that air when compressed shows a higher temperature than it had before, but resumes its initial temperature on the pressure being removed. Professor Smyth proposes to compress air, and cool it while under pressure; so that on regaining its original bulk, the temperature shall be less than that of the external air.

CO-OPERATIVE SYSTEMS. There seems to be a longing in modern society for the discovery of some new mode of remunerating the workman for the skill and labour which he bestows on manufacturing operations. Under the usual arrangements the employer agrees with the workman for a certain money payment, determined either on the quantity of work done or on the number of hours engaged: in other words, by 'piece-work' or by 'day-work.' The relative supply and demand of work to be done and of persons to do the work, is almost the only condition which determines the amount of wages to be paid for labour. It is wished at the present day, and

it has often been wished in former periods, that some mode could be devised by which the workman would have a deeper personal interest in the success of the firm for which he works, than he now has; that some sort of partnership system could be introduced, which would make the workman a partner on a humble scale, and yet leave to the capitalist and to the skilled superintendent a proper degree of liberty and of remuneration. Something of this kind is observable in the system on which the Cornish miners work; and many earnest persons are endeavouring to test the practicability of applying a similar system to manufactures generally.

If any clear and undoubted result had yet developed itself, we would briefly review the subject in this place; but the attempts hitherto made are too much in their infancy for us to do more than point out a few sources where the reader can obtain information on both sides of the question. Among the works we would name are Mr. Babbage's "*Economy of Machinery and Manufactures*"; Mr. Mill's "*Political Economy;*" "*Companion to the British Almanac,*" *for* 1851; "*Report of the Committee of the House of Commons* on the Savings of the Middle and Working Classes," in 1850; "*Edinburgh Review,*" January 1851; and the *Reports* of various co-operative associations.

COPAIBA or COPAIVA, is a resin or turpentine produced from several species of a tree grown in South America and the West Indies. It varies in appearance and qualities according to the species from which it has been procured, and likewise according to the age of the tree and the time of the year. Incisions are made in the tree, from which flows a liquid differing little in consistence from thick sap. It is collected in calabashes, after which the incisions are closed with wax or clay. The incisions are repeated in general three times each season. The fluid is brighter or darker in colour, more or less rich in volatile oil, more acrid or more bitter, according to circumstances. It is mostly of a light yellow colour, clear and transparent, seldom turbid or cloudy; odour peculiar, volatile; taste oily, mild, slightly aromatic, at last acridly bitter. In a state of purity, it consists of a volatile oil, in the proportion of 40 to 45 per cent., and 50 per cent. of an acid crystallisable resin. It is frequently adulterated with castor-oil, almond, poppy, nut-oil, and the finer sorts of turpentines. Good copaiva should be perfectly soluble in alcohol of the strength of 90 per cent. It is soluble in all known æthers, and in the volatile and fixed oils.

Copaiva is a valuable ingredient in many medicines. It is imported in casks containing 100 to 150 lbs. each, in large bottles, or in cylindrical tin boxes.

COPAL, a resin, the produce of the *Rhus copallinum*, a native of Mexico; it is in rounded masses, smooth and brittle, nearly transparent and colourless; it has but little taste, and is nearly inodorous; it is insoluble in water, fusible, and inflammable.

Copal varnish is prepared from copal and oil of turpentine. It is exceedingly durable and brilliant; it resists scratches, and is susceptible of a fine polish. There are several modifications of this varnish used for particular purposes.

COPENHAGEN. The trade of Copenhagen is considerable, but stationary rather than improving. The imports are chiefly sugar, coffee, cotton, rice, tobacco, potash, train oil and blubber, iron, salt, wool, dry and salt fish, pitch and tar, flax, hemp, oranges and other fruits, wine, brandy, rum, coals, &c. The exports consist of corn, flour, rape and other seeds, butter, cheese, beef, pork, cattle, wool, hides, bones, spirits distilled from corn, peas, beans, &c. A foreigner cannot trade as a merchant without becoming a burgher, which costs 100*l.* The industrial establishments of the city are numerous; they consist of brandy distilleries, breweries, vinegar distilleries, sugar refineries, soaperies, tanneries, iron foundries; cloth, cotton, silk, linen, and tobacco factories; besides ropewalks and extensive workshops for the making of hats, gloves, &c.

Copenhagen is preparing a collection of its produce and manufactures for the Hyde Park Exhibition.

A few details illustrative of the commerce of Copenhagen are given under Denmark.

COPING. This name is applied to the stone or brick covering of a wall, intended to protect it from the weather. Flat coping is called *parallel coping*, and is used upon inclined surfaces, as on the gables and parapets of houses, and also on the tops of garden and other walls. *Feather-edged* coping has one edge thinner than the other. *Saddle-back* coping is thicker in the middle than at the edges. Coping-stones should project over the walls which they cover, and should have a groove or *throating* underneath the projected part to throw off the water. The coping of Gothic battlements, and the walls of churches, castles, and dwellings in the Gothic style of architecture, have a deep throating in the form of a bold cavetto in front, and are sometimes decorated with mouldings.

In South Wales, near the copper-smelting town of Swansea, very durable coping, of a semi-cylindrical shape, is made from the hard slag of the copper-works, cast into moulds.

COPPER AND ITS MANUFACTURES. Copper is one of the metals with which the Greeks were acquainted; it was used by them, alloyed with tin, for cutting and warlike instruments, before iron was known, or at any rate before it was common.

Copper has a red colour, and is capable of receiving a good polish; when warmed or rubbed, it emits a disagreeable smell, and it imparts a nauseous taste: all its preparations are poisonous. It is both malleable and ductile, and is so tenacious, that a wire $\frac{78}{1000}$ of an inch in diameter supports a weight of 302 pounds without breaking; it is extremely sonorous, and is a good conductor of heat and electricity. It melts at a temperature about 1196° Fahr.

This metal is one of those which occur in the greatest number of places and in the largest quantity. It is found in small proportion in a metallic state, both crystallised and non-crystallised. Its ores are very numerous, the chief being sulphuret of copper and iron (Copper Pyrites), and sulphuret of copper (Nitreous Copper Ore). It occurs also naturally in some oxides and salts.

Copper pyrites occurs in the north of Europe, in England, especially in Cornwall, Devonshire, and Anglesey, and in many parts of Asia and Africa, and the American continents.

In 1844, a vein of very productive copper ore was discovered in South Australia. In 1846 the owners of the Capunda mine shipped to England 1200 tons of copper-ore, which sold for 25*l.* a ton, while English copper ore brought only 19*l.* But the Burra-Burra mine is perhaps the richest in the world. It contains a layer 17 feet high and very wide, which is worked like a quarry. The ore is a pure oxide of copper, and fit to be put at once into the smelting forge, and yielded in 1846 from 35 to 75 per cent. of pure metal. In July 1846, several tons of ore from this mine were sold at Swansea for 31*l.* 11*s.* a ton; and during the six months preceding May 1847, 2700 tons were raised from the same mine, which yielded 87 per cent. of pure copper, and sold for 31*l.* a ton. The shares in this mining company, on which only 5*l.* have been paid, now command a price of more than 200*l.*; and even at that price they yield a very large dividend. Such is the facility of working the Burra-Burra mine, that in 30 days 8 miners dug out 80 tons of ore. The copper ore exported from South Australia in six years was as follows:—

1843............	20 tons.
1844............	422 „
1845............	1158 tons.
1846............	6609 „
1847............	9301 „
1848............	17006 „

There seems to be remarkable evidence of the existence of large masses of native copper around the shores of Lake Superior. One such piece was met with a few years ago, at Outanagon, which weighed two tons; but a Toronto newspaper, in 1846, gave an account of a mass of copper, far exceeding in bulk any piece of native metal, probably, yet seen in the world. The miners had excavated 90 feet horizontally without coming to the end of its length; they had sunk 4 feet without finding the limit of its depth; but the thickness was about 1½ feet. The part exposed to view was estimated to weigh 80 tons, and to be worth 25,000 dollars. It was stated that machinery was about to be erected for sawing the block into moderate pieces, as the only mode of removing it from its bed. Since that time further indications of the richness of this store have been obtained; but the country is so scantily supplied with roads, that some time will elapse before mining operations can be regularly carried on.

The copper of England is chiefly produced from copper pyrites, yielded by the mines of Cornwall and Devonshire. As coal is scarce in those counties and plentiful in South Wales, the ore is conveyed to the latter district for smelting.

The first process in smelting copper is to calcine the ore; this is done by heating it in a calcining oven, which expels the arsenic and the sulphur contained in the ore, oxidises the copper and the iron, and reduces them to a black powdery state. This powder is then melted in a highly heated oven; and when liquid the mass is well stirred, to allow the metallic sulphuret to separate from the earthy matter. This metallic sulphuret is drawn off into a vessel of water and granulates into *coarse metal*, which is, weight for weight, four times as rich in copper as the original ore. The coarse metal is again calcined, and again melted; if drawn off into water, it obtains the name of *fine metal*, but if into sand, *blue metal*: it now contains 60 per cent. of copper (the coarse metal having about 33 per cent.). Another calcination and another melting bring it to the state of *coarse copper*, which contains 80 to 90 per cent. of pure copper. This coarse copper is exposed to a high heat in a roasting furnace, by which volatile matters are expelled, and the metals become oxidised; it is kept in a melted state for many hours, and is drawn forth from the furnace as *blistered copper*, almost wholly free from sulphur, iron, and other impurities. The blistered copper is transferred to a refining furnace, covered with charcoal, and is brought to a liquid state. It is thus rendered tough and malleable, and fit for subsequent manufacturing processes.

Attention has for some years been directed to the commercial advantage of smelting copper-ore by electric agency. Several years ago, Messrs. Claubry and Dechaud submitted to the French Academy of Sciences a plan in which the ore was first to be converted into a sulphate of copper by ordinary chemical means, and then the copper precipitated from a solution of this salt by electricity. In 1843 and 1844 Mr. Wall took out patents; and Mr. Ritchie, in 1844, took out another patent, having similar objects in view, namely, to separate the pure copper from the impurities of the ore, while in either a melted or a liquid state, by electric agency. Electro-smelting however has not yet been practised to any considerable extent.

Various important applications are made of copper in the state of sheets or rolled copper. Copper, like most of the unmixed metals, is generally rolled hot, being malleable at all degrees of heat till it approaches its melting point. Most of its alloys with zinc, forming brass, are malleable only when cold, with the exception of one or two lately brought into use, which are extremely malleable at a certain high temperature. Copper for the purpose of rolling leaves the smelting works in cakes about 12 × 18¼ inches, each weighing about 90 lbs. The cakes are put into *muffles*, where they are uniformly heated; and the heated copper is drawn between cast-iron rollers. This double process of heating and rolling is repeated until the cake of copper is reduced to the form of a sheet. An oxide forms on the surface during these operations; but this is easily removed by the application of a saline liquid, aided by heat. The edges are then trimmed, and the sheet copper is fit for application to manufacturing purposes.

Copper forms valuable alloys with other metals. Those which result from its union with tin and with zinc are the most important, such as *Bronze*, *Bell-Metal*, and *Brass*. *Tutenag* is an alloy of copper, zinc, and a little iron. *Tombac*, *Dutch Gold*, *Similor*, *Prince Rupert's Metal*, and *Pinchbeck*, are alloys containing more copper than exists in common brass. *Manheim Gold* is a peculiar alloy of copper and zinc, which is said to consist of three parts of copper and one part of zinc. *Packfong*, or the white copper of China, is an alloy of copper, nickel, and zinc, now extensively employed in this country under the name of *German Silver*.

The compounds of copper with non-metallic substances are numerous and important. The *oxides* are often employed to give a blue colour to other substances. The *sulphuret* constitutes one of the most valuable ores of copper. *Acetate of Copper*, more commonly known as *verdigris*, is much employed in painting, dyeing, and calico-printing. The *Arsenite of Copper* forms *Scheele's Green*, a well known valuable pigment. *Green Verditer* and *Refiners' Verditer* are obtained from *Carbonate of Copper*, and *Blue Verditer* from the *Nitrate*. *Sulphate of Copper*, under the name of *Blue Vitriol*, is largely employed by colour makers, dyers, and others.

The principal peculiarity of manufactures in copper arises from the facility with which it may be fashioned by the hammer. The processes of casting and rolling, both of which are extensively practised in the manufacture of copper goods, so closely resemble the like operations upon other metals, that they do not require further notice; but the operations of the coppersmith are very distinct from any other branch of metallic manufactures. For example, in the manufacture of the lower half or hemisphere of the large vessels called *sugar-pans*, used in sugar-refining, the copper is in the first place cast into a form resembling that of a double convex lens, or spectacle-glass, thickest in the middle, and diminishing gradually towards the edges. This lens is then subjected to the powerful blows of a tilt-hammer, directed more continuously near the centre than near the edges. This hammering while it reduces the thickness of the copper, makes it curl up at the edges, and assume a dished or hollow form. Another process no less peculiar to the manufacture of copper is the hammering, technically called *planishing*, by which the metal is rendered dense and firm, and its toughness is increased. Any one who examines a large copper vessel will perceive, both in the hammer-marks and in the density and close grain of the surface, evidences of the planishing process.

It is by the combined operations of casting, rolling, hammering, and planishing, aided by the fastening processes of riveting and soldering, that nearly all articles of copper are made. There are five different modes of forming copper piping out of sheet metal; in the first the edges of the sheet, which is curved round a mandril, are made to meet without overlapping, and united by a hard solder; in the second they overlap, and are united by soft solder; in the third they overlap, and are secured by rivets: in the fourth the edges are folded one over another, and made close and firm by hammering; while in the fifth both edges of the pipe are turned back, and covered with a strip of sheet metal, the two edges of which are turned in and hammered down.

Copper was at first obtained in this country in small quantities in working the tin mines in Cornwall; but about the close of the 17th century mines were set at work purposely for copper. Improvements in the art of smelting have greatly increased the products of the mines, and ores which produce only three or four per cent. of metal are now smelted. The average annual produce of the Cornish mines was only about 3,300 tons in 1780; the later produce we shall presently have to mention. The value of the produce of all the British copper-mines is in good years about 1,500,000*l.* Four-fifths of the whole quantity is raised from the Cornish mines; the rest being derived from Devonshire, Staffordshire, Anglesey, and the Isle of Man.

The duty on foreign copper ore, previous to 1842, was 12*l.* a ton, and on smelted but unwrought copper 27*l.* a ton; these rates were greatly lowered in 1842, and were reduced to merely nominal amounts in 1848.

The Cornish copper-ore sent to Swansea to be smelted, from 1820 to 1850, has varied from 100,000 to 160,000 tons annually. The quantity has gradually increased, but the quality of the ore has deteriorated. The selling value of this ore for the last few years has been from 800,000*l.* to 900,000*l.* Between 1844 and 1848 the foreign copper ore smelted at Swansea varied from 36,000 to 47,000 tons annually. The whole of the ore, British and Foreign, smelted at Swansea during the sixteen years from 1833 to 1848, has yielded the following averages:—

Average quantity smelted ..	.. 194,142 tons.
Average price per ton ..	.. £7 7*s.*
Average money value ..	.. £1,424,818
Average produce of copper ..	18,567 tons.
Average richness of ore	.. 10½ per cent.

In 1848 four firms at Swansea purchased and smelted no less than four-fifths of all the British and foreign ore smelted in Great Britain; the firms were those of Messrs. Williams and Foster, Messrs. Vivian, Messrs. Simms and Willyams, and Messrs. Grenfell; and the value of the ore purchased by them exceeded 1,100,000*l.*

COPPERAS. The sulphate of copper is frequently called *Blue Copperas*, the sulphate of iron *Green Copperas*, and the sulphate of zinc *White Copperas.*

COPYING MACHINES. Copying Machines are extensively used in mercantile establishments for producing duplicates of letters, invoices, and other manuscript papers. The most simple contrivance acts by transferring, by means of a rolling or screw press, a portion of the ink with which a letter is written to the surface of a sheet of blank paper prepared to receive it by damping. The transfer thus obtained is of course the reverse of the original letter, and, unless it be taken on paper so thin and transparent that it may be read through it, it must be read backwards. Watt's copying-press was a contrivance for obtaining transfers of this kind upon thin unsized paper, wetted, and then placed between two woollen cloths, which absorbed all unnecessary moisture. Elegant screw presses of iron are manufactured for this purpose; some having the power applied solely by means of a screw, turned by a transverse bar or lever, or by a cross or wheel-shaped handle; while others have also a contrivance for increasing the pressure beyond what can be conveniently applied by the simple turning of the screw. In some cases, letters intended for transferring by the copying-press are written with an ink made for the purpose; and when common ink is used it may be thickened by adding a little sugar to it. Transfers are also taken from the pages of a manuscript book prepared for the purpose, a sheet of dry oiled paper being placed over the damp sheet to prevent the transmission of the moisture.

Contrivances for enabling a person to write with two pens or pencils at once, on different sheets of paper, on the principle of the PANTOGRAPH, have been tried as copying-machines, but they are too complicated for ordinary use. All such machines, and perhaps even the copying press, are far surpassed in convenience by the *Manifold Writer.* In this apparatus a sheet of paper blackened on both sides with printers' ink, and dried for five or six weeks between sheets of blotting-paper, or covered with some other black composition which will come off when pressed hard, but will not move with a slight degree of pressure or friction, is laid between two sheets of thin writing-paper, and the whole is placed upon a smooth copper or pewter plate. The letter is then written firmly on the upper sheet of paper with an agate style or point, the pressure of which causes the blackened paper to produce two impressions of the writing, one, which is read through the paper, upon the under side of the sheet directly acted upon by the style, and the other upon the upper side of the lower sheet. More than two impressions of the writing may be obtained by using two or more sheets of blackened paper, interposed between several sheets of thin white paper. This apparatus is conveniently fitted up in a small portfolio, and occupies no more room than an ordinary writing-case.

In a machine recently registered by Messrs. Mordan, a stamping press is combined with an ordinary copying machine. When worked in the customary way, the platten rises with the screw, leaving a space beneath it for the copying process; but by a little adjustment the screw is raised without the platten, leaving a die and counterdie in proper position for stamping any device on letters, envelopes, or papers.

COPYRIGHT OF DESIGNS. [Designs, Copyright and Registration.]

CORAL AND THE CORAL FISHERY. Coral consists of the cells or habitations of minute animals, so built up as to form a tree-like structure. Being beautiful in form and colour, it is sought after for purposes of ornament; and its fishery or gathering gives employment to many persons in the Red Sea, the Persian Gulf, the Mediterranean, and other places. In the Straits of Messina, the rocks which yield coral are from about 350 to 650 feet below the surface of the water. The coral here grows to about the height or length of twelve inches, and requires eight or ten years to come to perfection. In the general mode of fishing for coral, the instrument used consists of two heavy beams of wood, secured together at right angles, and loaded with stones to sink them. Hemp and netting are attached to the under side of the beams, to the middle of which is secured one end of a strong rope, by which the apparatus is let down from a boat, and guided to the spots where the coral is most abundant. The branching form of the coral causes it to become entangled in the hemp and network, by which means it is broken off from the rock, and drawn up with the apparatus to the surface of the water.

CORBEL, in building, is a projecting piece of stone, wood, or iron, placed so as to support a weight of materials. Corbels are sometimes in the form of the modillion or mutule employed in entablatures, and also like the console of a window. The machicolations of towers are almost always supported on corbel stones, as may be observed in the old gates of Southampton, Canterbury, and York. In Norman architecture the cornice is supported by a row of corbel stones, the ends of which are carved. In old English castles the main beams of the floors were frequently carried on large corbel stones, as at Porchester Castle. The term bracket is sometimes used for a corbel.

CORDIALS. A cordial is generally one of the many kinds of spirit, flavoured with sweetening and aromatic substances. A distiller who produces raw spirits from corn or malt, is not allowed by the excise laws of this country to give any additional or artificial flavour to his spirit; he must sell it in the crude ardent state in which it leaves the still. This is not done out of any consideration in which the consumers are concerned, but simply as a matter of revenue. The distillers rarely if ever sell spirit to the public generally. It is sold to the *rectifiers*, who re-distil it, and impart flavour to it by various means. Cordials are among the liquors which are so treated. Some are made simply by adding essential oils and syrup to diluted spirit; while others are made by adding aromatics to the spirit, boiling and re-distilling it, and sweetening the re-distilled liquor. Some cordials are made from raw spirit, but the best from rectified spirit of wine.

The various cordials are known by the names of the vegetable substance to which they chiefly owe their distinguishing flavours. Hence we hear of Aniseed, Caraway, Cedrat, Cinnamon, Citron, Clove, Coriander, Lemon, Lovage, Orange, Peppermint, and other cordials.

CORFU. A few details illustrative of the industry and commerce of this island will be found in connexion with the group of which it forms a part [Ionian Islands.]

CORIANDER, is an annual umbelliferous plant, inhabiting the southern parts of Europe and yielding a globular dry fruit, with slight carminative stomachic properties and a powerful smell.

Coriander fruit, or *seeds* as they are incorrectly called, are used in sweetmeats, in certain stomachic liquers, and in some countries in cookery.

CORK. The county and city of Cork are both worthy of attention, in respect to natural products and commercial pursuits. The principal copper-mines in Ireland are situated at Allahies in this county. They were first worked in 1814. The ore contains from 55 to 65 per cent. of copper. In the same neighbourhood the ashes of a bog impregnated with copper yielded a considerable return until burned out. A deposit of manganese is worked with good profit on the same coast. Veins of sulphate of barytes occur in the neighbourhood of Bantry, and specimens of asbestos have been procured at Beerhaven. The iron-ore is abundant, and when timber was plentiful, many iron-works were carried on. There is good anthracite coal in the Blackwater district; but it is so difficult of access, that it has not yet been made available for the smelting of iron. The principal trade of the county is the export of agricultural produce, such as grain and butter. The linen and woollen manufactures at one time flourished in several towns of this county; but trade in these branches has for many years back been languishing.

In the city of Cork, the manufactures are of little importance compared wiih the trade and commerce. There are tanneries, iron-foundries, glass-houses, distilleries, and breweries. The export trade consists principally of grain, butter, and other provisions, and cattle; the import trade of timber and the various articles required for the use of the city and the surrounding neighbourhood. Steamers ply daily between Cork and the harbour at Cove; and large steamers trade regularly with Dublin, Belfast, Liverpool, Bristol, and Glasgow.

The principal harbour of Cork is at Cove, about 9 miles below the city, but lighters of 30 tons' burthen come up to Patrick's Bridge, on the north branch of the river, where there is a fine line of quays. Merchant-vessels unload into the lighters at Passage, about 6 miles down the river. The harbour at Cove is 3 miles long and 2 miles wide, completely sheltered and protected by forts on various points. The entrance is 2 miles long and 1 mile wide. 600 merchant-ships have been at anchor in it at once, and 400 have left it under convoy in one day. The colonial trade is chiefly with Canada; the foreign with Portugal, the Baltic, and the Mediterranean.

The butter trade of Cork is very extensive, and is conducted on a remarkable system. There is a committee of members to superintend all the dealings between buyers and sellers. All the butter brought to market is inspected and branded by orders of the committee, and is divided into four classes, according to its quality. A sub-committee each morning fixes the price at which each kind of butter shall be sold on that day; the four kinds differ in value about 5*s.* per cwt. from each other. The number of firkins branded in certain years was as follow:—

1770..........	105,809	firkins.
1800..........	183,249	„
1830..........	277,947	„
1850.. (about)	400,000	„

The butter buyers are in the habit of advancing money before-hand to the dairy farmers; so that sometimes a whole season's produce is thus paid for before any of the butter is made.

CORK CUTTING. The nature of cork is explained in an earlier article [BARK]. In the making of ordinary corks, the material is entirely shaped by very sharp, smooth-edged broad knives, without the aid of any machinery; it is one of those employments in which everything depends on the manual skill gradually acquired by the workman.

The attempts to make corks by machinery have been very numerous. In one among several American patents for this purpose the quadrangular pieces of cork, cut to proper lengths, are held between two revolving spindles which grip them; and as they revolve, the cork is cut round by a revolving cutter-wheel, the arbor of which is horizontal and has its bearings in a sliding frame. Other apparatus allows the spindles to disengage the cork when cut. The edge of the cutter-wheel is kept sharp during the operation by means of two rotating discs, one acting on each face, and each covered with leather and emery. The blocks or pieces of cork are placed in a box, from which they are taken by a jaw which slides forward and places them between the grips of the revolving spindles.

Another plan was patented a few years ago by Messrs. Cutler and Hancock. A horizontal spindle, running in suitable bearings, carries a hollow conical cutter at each end. The largest end of the cone, which is outwards, is made very sharp; and a small opening lengthwise of the cutter has also a cutting edge, for reducing the cork to a proper size and shape, as it enters the cone. A convenient number of these spindles are mounted in a frame, to which a traversing motion can be given by means of a screw and handle. A rapid motion is communicated to the spindles by a number of belts from a large drum moved by a steam engine or other source of power. Pieces of cork are placed in a holder; and the holder being placed in front of the cutters, with a proper support behind, they are urged forward by the hand screw until the cork has been cut through. The corks, as they are made, are pushed out by rods, which slide within the spindles.

A 'Patent Cork Cutting Company' has been lately established, for the manufacture of corks by machinery. The patentees assert that the corks so made are both cheaper and better than those made by hand,—a matter which will soon be determined by the purchasers. The same company manufacture cork gun-wadding, used in military services.

Many substitutes for cork have from time to time been introduced,as stoppers for bottles. Mr. Brockedon has invented bottle-stoppers made of india rubber. The core of the stopper is made of cotton twisted into strands; several of the strands, lapped with flax thread, are laid together longitudinally, with loose fine cotton roving laid between them. They are then lapped in a cylindrical form with flax thread, and the india-rubber solution applied to it while warm. It is only for peculiar purposes that these stoppers can be used as substitutes for corks; when applied, they must be slightly wetted to make them slide down the inner surface of the neck of the bottle.

Mr. Betts, the distiller, has introduced a patent capsule, for stopping bottles containing patented and other liquors. The material employed consists of thin plates of metal, formed of a layer of tin united to a layer of lead; and this material is brought to a shape which enables it entirely to cover the corked mouth of the bottle.

One of many modes suggested of employing cork for stuffing beds and cushions is that patented a few years ago by M. Bachelard. According to this suggestion, the cork is used in the state of saw-dust or shreds, instead of in bulk. Any mode of preparing it may be adopted, provided it be in very small fragments. It may be used alone, or combined with wool or horsehair. The patentee states that if a substratum of the cork be covered with a layer of horse-hair or wool, we shall have all the smoothness of a horse-hair or wool mattrass, combined with the lightness and elasticity of cork. When used at sea, such a mattrass might be light enough to act as a life-preserver, in case of exigency.

The unmanufactured cork imported in 1848 amounted to 3,028 tons. The French corks imported in a manufactured state amounted in 1849 to 151,861 lb.

CORKSCREW. The common corkscrew is too simple in its action to require any description; but that which goes by the name of its inventor, and is called the *Shrapnell Corkscrew*, deserves a little notice.

The Shrapnell Corkscrew, though specially adapted for the Shrapnell bottle, is also useful for other bottles. This corkscrew has three spikes, which press down vertically on the upper surface of the cork soon after the screw has entered. As soon as the spikes touch the cork, they are prevented from turning round with the screw, and they thus enter the cork as the screw rotates. When the cork is about to be extracted, a slight twist given to the instrument enables the extraction to take place with much ease. The Shrapnell bottle is intended to obviate the necessity of using wire or string for fastening down the corks of bottles which contain effervescing drinks. The inside of the neck of the bottle is cut or cast with an internal screw; so that the cork, driven in in the usual way, expands in the screw, and holds so tightly that nothing but a circular or screw-like movement, such as that of the Shrapnell corkscrew, can remove it.

CORN TRADE. The name of *corn* is sometimes given to grain only, while at other times it is made to include meal or flour as well as grain. The American merchants, and some in our own country, give the name of *breadstuffs* to grain and meal collectively. We shall give a few entries illustrative of the consumption of foreign corn in this country.

The wheat and wheat flour imported into Great Britain between the years 1825 and 1849, varied from 66,905 qrs. in 1835, to 4,835,280 qrs. in 1849. Of the quantity in this last mentioned year, which exceeded that of any previous year, the imports from the chief sources of supply were in round numbers:—

France	750,000 qrs.
United States	600,000 "
Russia	600,000 "
Prussia	600,000 "

The average importation of wheat and wheat flour, from 1828 to 1849, was 1,771,067 qrs. annually; of which Prussia supplied 435,791, United States 242,094, Germany 232,034, and Russia 209,237.

The quantities of all kinds of grain and meal imported in 1849, were as follow:—

Wheat and wheat-meal	4,835,280
Barley and barley-meal	1,389,858
Oats and oat-meal	1,307,904
Rye and rye-meal	246,843
Peas and pea-meal	236,525
Beans and bean-meal	458,651
Indian corn and meal	2,277,224
Buckwheat and meal	627
Beer or Bigg	843
	10,753 755

The average prices paid for six of these varieties of foreign corn and pulse in that year were—wheat 44*s.* 3*d.*, barley 27*s.* 9*d.*, oats 17*s.* 6*d.*, rye 25*s.* 8*d.*, peas 31*s.* 2*d.*, beans 30*s.* 2*d.* per quarter.

The wheat, barley, and oats, sold in the towns from which the averages given by the corn inspectors are obtained, in three consecutive years, amounted to the following quantities:—

	Wheat.	Barley.	Oats.
1847	4,637,616	2,041,129	960,334
1848	5,399,833	2,401,736	1,022,875
1849	4,453,982	2,099,820	851,079

In the year 1850, the following enormous quantities of 'bread-stuff' were brought into the port of London, from the agricultural counties and from abroad:—

Wheat	874,410 quarters.
Barley	455,475 „
Oats	1,141,398 „
Beans	122,226 „
Peas	76,255 „
Flour	399,123 sacks and 66,463 barrels.

More than three-fourths of this entire quantity was brought from foreign countries. In 1849 the quantities of wheat, barley, and oats, exceeded those of 1850.

CORNELIAN, or CARNELIAN. [AGATE.]

CORNET was an ancient wind instrument formed of wood; it was superseded in the latter part of the 17th century by the oboe.

CORNET-STOP, in the organ, is an imitative treble-stop, consisting of five ranks of pipes, each key of the instrument causing all the five pipes to sound at once; they are tuned to a given note and its 8th, 12th, 15th, and 17th.

CORNWALL. Copper and tin are the most important minerals of Cornwall. The extent of the metalliferous veins is unknown, as well as the depth to which they extend: no miner has yet seen the end or bottom of a vein. Their width varies much, from the thickness of a sheet of paper to 30 feet; but they are usually from 1 to 3 feet in thickness. The ores of copper or tin do not often occur together in the same vein at any great depth. If tin be discovered first, it sometimes disappears, after sinking 100 feet more, and is succeeded by copper; in others, tin is found at the depth of 1000 feet beneath the surface, almost without a trace of copper; if copper be first discovered, it is very rarely, if ever, succeeded by tin. It is seldom that either ore is found nearer to the surface than 80 or 100 feet.

The copper and tin mines, excepting a few near Callington, are south-west of the rivers Alan and Fowey. The chief mining district extends from St. Agnes on the north coast by Redruth to the neighbourhood of Helston and Marazion; and some mines are worked west of Marazion. St. Austell is in the centre of another but less extensive mining district near the south coast.

The lead mines of Cornwall are not numerous, though the ore has been discovered in many parts of the county. Silver ores have been obtained from several mines in Cornwall, chiefly in lodes or cross courses in the graywacké. Gold has been found in the tin streams. Iron ore is also obtained, and shipped to Wales. Zinc, antimony, cobalt, and arsenic are procured, as well as some other of the semi-metals. Freestone of different qualities is quarried.

During the 30 years from 1815 to 1845, there were 220 copper mines in the county, the produce of which was sold at the public ticketings. In the year 1845, 35 of these mines had been worked upwards of 20 years; 40 had been worked between 10 and 20 years; 31 had been worked between 5 and 10 years; and 114 had been worked less than 5 years. The average per-centage of copper from all the mines during the 30 years was 7⅝; the highest average from any one mine was 26¼; and the lowest average from any mine was 2⅝. The quantity and value of Cornish ores are briefly alluded to in another article [COPPER].

The following demands for space at the Great Exhibition, whether fully adhered to or not, will serve to illustrate the products and resources of Cornwall:—In the first section (raw materials and produce) for the mineral kingdom will be required—for ores, 398 superficial feet; for models of machinery, illustrating the preparation of the ore for the smelter and tin smelting, 70 feet; ochres, clays, and china stone, including a model of a clay-work, 94 feet; building and road stones, sand, hone stones, &c., 171 feet; ornamental stones and slates, 202 feet. Animal and vegetable kingdoms—for hides, 100 feet; pilchards, 4 feet; Normal guano, 3 feet; wheat, 2 feet—109 feet; for nets illustrating the Cornish fisheries, 150 feet; making a total required in section 1, 1,194 feet. In the second section (machinery) are required for steam-engines and instruments connected with steam machinery, 784 superficial feet; miscellaneous machines, models, and tools, 204 superficial feet; naval architecture, 70 superficial feet; total in second section, 1,058 superficial feet. For the display of manufactures 412 feet of space have been demanded, 336 feet of which are required for ornamental manufactures in granite, porphyry, serpentine, riband slate, &c., the remainder being wanted for crucibles, safety fuze, chairs, embroidery, &c. Making a total of space required for the county of 2,664 superficial feet.

CORRIDOR signifies a gallery or passage-way leading to apartments independent of each other. In all large buildings containing numerous apartments corridors are necessary, either closed or open. The corridor round the great cortile, or open court, of the Cancellarea at Rome, designed by Bramante, consists of an open gallery supported by columns.

CORSICA. About 25,000 acres in this island are planted with vines. The yearly produce of wine is 6,000,000 to 7,000,000 gallons, some of which, especially that of Cap Corso, is of good quality; but in general it is carelessly made, ripe and unripe grapes being put indiscriminately into the wine-press. Of chestnuts, an important article of food, the produce is about 50,000 quarters; the chestnut-tree is one of the most magnificent vegetable productions of the island. The mulberry is cultivated for the production of silk. The cotton-shrub, sugar-cane, indigo, tobacco, and madder are also cultivated. The orange, citron, fig, almond, pomegranate, date-palm, and other fruit-trees, flourish, and their produce is largely exported. The chestnuts and walnuts of the island are of the best quality and of the largest size. A good deal of excellent honey and wax is gathered.

Iron, lead, antimony, black manganese, granite, varying in colour from gray to red, porphyry, white marble, limestone, jaspar, emerald, amianthus, &c., are found. Of manufacturing industry there is little. A little iron is manufactured from ore brought from the island of Elba, for no mines are worked by the Corsicans. The island has several oil and flour mills, tanneries, and brick-works; 2 establishments for the manufacture of soap, and 1 for making glass. These articles, together with turnery, pitch and tar, and bad cheese, are almost the only industrial products. The commerce consists of the agricultural produce, and brandy, olive oil, dried fruits, wax, salt fish, coral, ship-timber, myrtle leaves, orange flowers, lichen, tanned hides, goat-skins, deals, &c.

CORUNDUM. Several substances differing considerably in colour, and sometimes in form, but nearly agreeing in composition, are classed together under the name of *corundum*, which is that given to the common variety by the natives of India. The *sapphire* is one of these substances; its chief varieties are the *white*, transparent or translucent; the *oriental*, blue; *oriental amethyst*, purple; *oriental topaz*, yellow; *oriental emerald*, green. The sapphire occurs in rolled masses and crystallised; it possesses double refraction, and is inferior in hardness only to the diamond. *Ruby* is of a rose-red colour, and generally occurs in six-sided prisms. *Common corundum*, or *adamantine spar*, is sometimes nearly colourless, and rather translucent; it presents great variety of colour, but is most commonly greenish or grayish, occasionally brown or red, rarely blue; it is used in the East Indies for cutting and polishing precious stones, and also granite and other hard rocks. *Emery* is regarded as amorphous corundum; its colour is usually gray; its lustre is somewhat glistening; when ground to powder, it is used in polishing hard bodies. Alumina forms about nine-tenths of all varieties of Corundum.

COSMETICS. The chemistry of the toilet-table has provided many preparations under the name of *Cosmetics*, for external adornment or artificial beautifying. *Hair dyes*, *pomatums*, *pomades*, *depilatories*, *dentifrices*, *tooth-powders*, &c., may all be deemed more or less as belonging to the class of cosmetics; but the name is usually confined to those preparations which are applied to the skin.

The best cosmetic is plain soap and water. To soften the skin, however, many substances are used, such as almond soap, Naples soap, Castile soap, milk of roses, cold cream, or almond paste. Sometimes it is desired to harden the cuticle or outer skin, and this is done by spirit, astringents, and acids. For removing or hiding freckles, various lotions and washes are employed. To give an artificial tint or bloom to the skin is the chief work of the cosmetic artist. Rouge and carmine are much employed to give a red tint: starch and magnesia to impart a delicate whiteness. Several of the salts of bismuth and of lead, under the various fine names of *pearl white*, *flake white*, *cream of roses*, &c., are often employed as cosmetics; but they have an injurious effect on the skin, and sometimes produce a sort of skin-poisoning.

A want of attention to the chemical action of colours has sometimes led ladies into an embarrassing predicament. Bismuth-powder, sometimes sold as a substitute for genuine pearl-powder, has the property of turning black when in contact with fumes of sulphur, or with sulphuretted hydrogen gas. A lady who painted with this cosmetic, happened to bathe in a mineral water impregnated with this gas; and the consequence was, that the artificially whitened skin turned nearly black, and so remained for several weeks. Another lady, who used the same cosmetic, attended a lecture at Harrogate on mineral waters; and the lecturer handed round a bottle containing sulphuretted water, that its odour might illustrate the point on which he was directing attention; the lady did as others did—smelt at the bottle; and the result was that she became, not merely figuratively, but literally 'black in the face.' Even the coals of a common English fire often contain enough sulphur to produce in a slighter degree an analogous effect. Instances have been known in which a lady, seated near a large fire at Christmas time, has had one side of her white neck tinged with a darkness which puzzled all, except those who were aware of the effect of sulphur fumes upon bismuth-cosmetics.

COTE-D'OR. This department of France

is famous for its wines. The favoured district is divided into two parts—the Côte-de-Nuits, extending from Dijon to Nuits; and the Côte-Beaunoise, from Nuits to the Dheune. The former is famous for its red wines, the most renowned of which are those called Romanée, Vougeot, Chambertin, Richebourg, and Nuits; while the latter produces both red and white wines, which for flavour, delicacy, and perfume, are not surpassed in the world; but they do not bear transport so well as those grown on the Nuitonne slope. Among the red wines of the Beaune slope, the most famous are those called Volnay, Pomard, Beaune, La Peyrieure; and among the white, Meursault, Montrachet, and Goutte-d'Or. Besides these famous Burgundy wines, a good deal of wine resembling Champagne is manufactured in the department, and sold as such. The annual produce of all the vineyards of the department amounts to about 12,000,000 gallons.

The department ranks the first in France with respect to the extent of its forests, in which oak, beech, and elm are the principal trees.

Iron, coal, marble, millstones, limestone, plaster of Paris, potter's clay, &c. are found. The iron mines, which lie chiefly in the mountains in the north-east of the department, are amongst the most productive in France; the ore is converted into malleable iron and steel at nearly 100 blast furnaces and foundries by means of charcoal near the mine-mouth. There are about 300 factories of various kinds in the department, the products being linen, woollen cloth, blankets, cotton and woollen yarn, beet-root sugar, brandy, vinegar, paper, seed-oil, beer, leather, and earthenware. The commerce of the department consists in the agricultural and industrial products already named, and in wool, hides, timber, oak staves, hay, fuel-wood, nails, and whetstones.

COTTON CULTURE AND TRADE. Cotton is a filamentous substance produced by the surface of the seeds of various species of *Gossypium*. It consists of vegetable hairs, of considerable length, springing from the surface of the seed-coat, and filling up the cavity of the seed vessel in which the seeds lie. These hairs are long weak tubes, formed from cells which have grown together, and which, when immersed in water and examined under the microscope by transmitted light, look like flat narrow transparent ribands, presenting at short intervals a spiral twist, by means of which their surface is roughened, so that cotton goods are less soft than linen.

The genus *Gossypium* is common to both continents. There is no record of the first cultivation of the cotton plant in Asia or America: it being indigenous to both, so far as our present knowledge extends. Africa and Europe are supposed to have first become acquainted with cotton by the exportation of muslin from India by way of the Red Sea. The various species occupy naturally a belt probably exceeding the torrid zone in breadth, but in a cultivated state we have cotton now extending on one hand to the south of Europe, and Lower Virginia, and even Maryland, in the United States of America; while, on the other, we have it as far south as the Cape of Good Hope, and in America to the southern parts of Brazil. Within these limits it may also be seen cultivated at considerable elevations. Baron Humboldt mentions having seen it even at 9000 feet of elevation in the Equinoctial Andes; and in Mexico, at 5500 feet. Dr. Royle states it as being cultivated in small quantities at 4000 feet of elevation in 30° N. lat. in the Himalayas. The localities suited to the production of cotton depend as much upon the climate as the soil, and also upon the specific peculiarities of the different kinds of cotton plants.

The distinctive names by which cotton is known in commerce are mostly derived from the countries of their production: the exceptions are Sea Island Cotton and Upland Cotton. The former of these was first cultivated in the low sandy islands near the coast of Charleston in America; while the latter is grown in the inner or upland country. The Sea Island Cotton is the finest of all the varieties of cotton. The Upland is often called Bowed Cotton.

In India and many of the islands of the Indian Ocean, the cotton-plant has been cultivated, and its filaments spun and woven, from time immemorial. In Mexico the Spaniards found cotton in common use at the time of their conquest of the country. The Egyptians were acquainted in the time of Pliny with the use of cotton. The cotton-plant was very early known in China, and cultivated as an ornamental garden shrub; but its filaments were not brought into use until about the 13th century. The Saracens cultivated cotton in Spain and Sicily in the 10th century. The manufacture of cotton did not rise in other countries till a much later period. It was not until the 17th century that cotton goods were made in England; and even of these the warp was composed of linen and only the weft of cotton, until the invention of Arkwright afforded the means of producing good fabrics of cotton only. From that date (1769), the trade in cotton in this country has gone on increasing with astonishing rapidity. The quantity of cotton brought to this country in 1744 was about 4,000,000 lbs.; in 1780, about 7,000,000 lbs.; in 1790, about 30,000,000 lbs.; and in 1800, about 50,000,000 lbs. The imports did not increase very rapidly during the war; but since that time they have augmented in the following manner, taking an interval of five years between the respective dates :—

Years.	Pounds.
1815	99,000,000
1820	152,000,000
1825	229,000,000
1830	264,000,000
1835	364,000,000
1840	592,000,000
1845	722,000,000
1849	775,000,000

Mr. Woodbury, the Secretary of the United States Treasury, has estimated the entire produce of cotton in all countries, at various periods, as follows :—

Years.	Pounds.
1791	490,000,000
1801	520,000,000
1811	555,000,000
1821	630,000,000
1831	820,000,000
1834	900,000,000

In 1791 the United States produced only $\frac{1}{25}$th of the entire quantity; in 1834 its share exceeded one-half; and in 1844 its produce was nearly double of that in 1834. More than half in value of the entire exports from the United States now consist in cotton wool. More than four-fifths of the entire cotton produce of the United States is purchased by Great Britain. In the Mississippi valley land fresh brought under cultivation will yield on an average from 1000 to 1200 lbs. per acre of cotton with the seed, which will yield 250 or 300 lbs. of cleaned cotton.

As there are frequently doubts entertained concerning the capability of the United States to supply us regularly with cotton, and concerning the prudence of depending mainly on one country for a supply, attempts are now being made to encourage the growth of cotton in the West Indies and Port Natal, and an increased growth in the East Indies. Many of these attempts seem likely to be attended with success. The experiments now being made in respect to flax [FLAX] were in like manner suggested by uncertainty concerning the American supply of cotton.

The imports of cotton in the years 1845-6-7-8 and 9, and placed under the names of the countries whence imported, were as follow, in bales :—

	1845—49.		Yearly average.
United States ..	6,188,144	..	1,237,619
Brazil	495,685	..	99,137
Egypt	224,579	..	44,918
East Indies ..	899,213	..	179,852
Miscellaneous ..	44,833	..	8,966
	7,852,454	..	1,570,492

A bale or bag of cotton has become a gradually increasing quantity. In 1820 it averaged about 250 lbs.; at present the average is somewhat above 400 lbs. Our imports, in lbs., were 717 millions in 1848, and 775 millions in 1849.

Nearly all the cotton used on the continent of Europe is grown in the United States. The average United States produce for the years 1844-50 has been about 2,200,000 bales—nearly a thousand million lbs.!

COTTON MANUFACTURE. Cotton was woven by the Hindoos and Chinese many centuries before the Christian æra. The Egyptians are supposed to have imported woven cotton before the plant had begun to be cultivated in their country; and the Romans received woven cotton from India long before the cotton-plant was known in Europe. The first Europeans who spun and wove cotton were the Italians of the commercial republics, who had become familiar with the material while exercising their trade as merchants between Europe and the East. From the 10th to the 13th centuries, cotton goods were manufactured to a large extent by rhe Moors of Spain, especially a coarse variety to which they gave the name of *fuste*, whence our 'fustian.' The other nations of Europe learned the manufacture of cotton, not from the Moors of Spain, but from the Christians of Italy. The art travelled from Italy to the Netherlands, and thence to England, where it was first practised in the beginning of the 17th century.

The extension of this manufacture has been far more rapid in England than in any other country. Before Arkwrigkt's time, it was the custom for the weavers, who were dispersed in cottages throughout the manufacturing districts, to purchase the material with which they worked, and, having converted it into cloth, to carry their wares to market, and sell them on their own account to the dealers; but about 1760 the merchants of Manchester began to employ the weavers, furnishing them with yarn for warp, and with raw cotton, which was spun by the weaver's family for the weft, and paying a fixed price for the labour bestowed in weaving. The Factory System, now so closely connected with the cotton manufacture, arose out of the invention of complicated pieces of machinery which could not be worked in the cottages of the weavers. About 1760 James Hargreaves invented a carding-engine, to assist in straightening the fibres of cotton. In 1767 the same ingenious man invented the Spinning Jenny, by which a number of threads could be spun as easily as one thread by the old spinning wheel. The saving of labour which this machine effected roused the jealousy of the spinners, who for a time prevented the new machine from coming into general use. This opposition however being overcome, the Spinning Jenny became generally used for spinning weft threads in the manufacture of cloth, wherein linen thread formed the warp. Arkwright patented in 1769 his Spinning Frame, by which cotton yarn could be woven strong enough for warp threads. All attempts to produce fine muslin, although India-spun yarn was used as weft, were for many years fruitless; but in 1786 Samuel Crompton invented the Mule Jenny, by which yarn could be produced much finer and softer than any before wrought in this country.

This train of inventions led to an astonishing increase of manufacture. But the manufacturers were for a time subjected to much discouragement from the determination of the revenue officers to charge for cloth composed wholly of cotton double the duty payable upon calicoes woven with linen warp and printed for exportation, and also by prohibiting their use at home. With some difficulty an act of Parliament was obtained for removing these obstacles to the development of the maufacture, which from that time was prosecuted with a great and continually accelerated rate of increase. Of the inventors who gave the spur to this industry, Hargreaves and Crompton died comparatively poor, while Arkwright was enabled to accumulate enormous wealth. Some of Crompton's finest yarns were sold by him at 20 guineas per lb.: they can now be produced of the same fineness for 15 shillings!

Arkwright brought out a succession of improvements in the various processes of the manufacture; and since his time every year has added to the number, until the preparing and spinning machinery has reached an extraordinary degree of perfection. The first successful attempt to *weave* by machinery was made in 1785 by Dr. Cartwright; and Mr. Monteith of Glasgow was the first person to make use of the new method on a large scale. Radcliffe added efficiency to the power looms by the invention in 1804 of the Dressing or Starching Machine.

The processes connected with the preparation and spinning of the cotton fibres are described under ARKWRIGHT; COTTON SPINNING; and THREAD. The weaving of the yarn into piece-goods is described under FUSTIAN; VELVET; and WEAVING. The imparting of colour and design to the woven cloth is treated under BANDANA; COTTON or CALICO PRINTING; and DYEING. The statistics of the manufacture, in respect to the number of factories, power-looms, work-people, &c., are given under FACTORIES. Mr. McCulloch estimates that, allowing for old persons and children dependent upon those actually employed in the various departments of the cotton manufacture, and in the construction and repairs of the machinery and buildings required to carry it on, the entire manufacture in Great Britain must furnish subsistence for at least 1,250,000 persons.

Mr. Kennedy estimated the value of the cotton manufactures produced in Great Britain in 1832 at about 25,000,000*l.* Mr. Baines made the estimate for 1833 at about 31,000,000*l.* Mr. McCulloch's estimate for 1836 was about 34,000,000*l.* Mr. Porter's estimate for 1841 was about 49,000,000*l.* It is admitted that there are no exact data for determining these quantities; but the above are approximately correct. The capital invested is supposed to amount to 30,000,000*l.* or 35,000,000*l.*

The real or declared value of manufactured cotton goods exported from this country in various years was as follows:—

Years.	£
1820	16,516,748
1825	18,359,526
1830	19,428,664
1835	22,128,304
1840	24,668,618
1845	26,119,331
1849	26,890,794

The exports for 1849 were thus divided:—

	£
Piece goods	18,834,601
Lace and net	487,300
Thread	427,422
Hosiery	118,418
Yarn	6,701,920
Sundries	321,133
	£26,890,794

Of this enormous value the portion sent to the British colonies amounted to 7,264,469*l.*

The cotton manufacture is now largely conducted in the United States, France, Belgium, Germany, and other countries; and specimens from all those countries will be found in the forthcoming Industrial Exhibition.

COTTON SPINNING. The spinning of cotton into the form of yarn, or thread, requires many preparatory processes. The first of these consists in mixing the contents of different bags together, to equalise the quality. This is done by spreading out the contents of each bag in a horizontal layer of uniform thickness, the contents of the several bags forming separate layers and resting one upon the other, so that the number of layers corresponds to the number of bags. The cotton of which this heap is composed is then torn down by a rake from top to bottom. It is evident that in its progress a portion of each horizontal layer will be brought away, and that thus, if the work be skilfully done, the contents of the different bags must be collected together in a mass of uniform quality. The mode of conducting the mixing depends on the quality of yarn required.

The *scutching-machine* is used to open the locks of cotton and separate its fibres, while at the same time it separates from it any sand or seeds which it may contain. This machine consists of feeding rollers made of wood, and placed at a short distance from each other, through which the cotton is made to pass slowly. After passing through the rollers the cotton is struck by a set of beaters made to revolve 1000 or more times in a minute. The cotton is passed through two sets of rollers, and subjected to two sets of beaters.

Up to this stage the fibres of the cotton cross each other in every direction. The use of the *carding-engine* is to disentangle them, to draw them out, and to lay them parallel to each other. The card is a species of brush made of short wires passed through a sheet of leather and pointing all in one direction. In the early period of cotton-spinning in this country, these cards were nailed on small pieces of board with handles, and two of them were used together, one held in each hand. Hargreaves invented an improved arrangement of cards in 1760; but this gave way to the cylinder machine, now universally employed. This consists of a horizontal cylinder covered with narrow fillet cards, studded with wires. Over the cylinder is a concave frame, the interior surface of which is lined with cards, and the form of which corresponds to that of the cylinder. When the cylinder is made to revolve, the cards on it and on the frame work against each other, by which means the fibres of cotton are disentangled and properly arranged, as already mentioned. The cotton is spread out into a sheet of given length and breadth, and placed so that the teeth of the carding-engine can catch it and draw it in. A sort of comb draws the fibres of cotton off the teeth when the carding is effected; and the cotton passes through two rollers into a tin can, where it assumes a light fleecy form called a *sliver*.

The next operation, that of *drawing*, has for its object the arranging of the fibres of cotton longitudinally, in a uniform and parallel direction, and to remedy all existing inequalities in the thickness of the sliver. The *drawing-frame* acts upon the same principle as Arkwright's spinning-frame, two sets of rollers being employed moving with unequal velocities. The cotton is drawn several times, to attain the utmost regularity.

Roving, the next step in the process, is a continuation of the drawing, with this only difference, that the cord, now called a *rove* or *slub*, being so much reduced in thickness that it will not otherwise hold together, a slight twist is given to it by passing it into a conical can, which, while receiving it, is made to revolve with great velocity. The rove, thus slightly twisted, is wound upon bobbins by children, and is then ready for the spinning-frame. The *fly-frame* and the *tubeframe* are two machines employed in this process.

The principle of Arkwright's *spinning-frame* has been already explained. [ARKWRIGHT.] The *throstle-frame* is the same in principle as Arkwright's invention, but the movement of the parts is simplified. A throstle-frame now contains from 70 to 150 spindles on each side; and one young woman can manage the double set, from 140 to 300 spindles. The Mule Jenny, invented by Samuel Crompton, combines the essential principle of Arkwright's frame with the property of stretching possessed by Hargreave's Jenny. By means of the mule-jenny, the roving is first drawn and then stretched. The effect of this improvement is to make the yarn finer, and of a more uniform tenuity. The spindles in this machine are regularly arranged on a carriage, which, when put in motion, recedes from the rollers with a velocity somewhat greater than that at which the reduced rovings are delivered from them; during this time the yarn is receiving its twist by the rapid revolving of the spindles, and when the rollers are made to cease giving out the rovings, the mule-jenny still continues to recede, but with a slower motion, and its spindles to revolve, and thus the stretching is effected. When the drawing, stretching, and twisting of the thread are thus accomplished, the mule disengages itself from the parts of the machine by which it has been driven, and then the attendant spinner returns the carriage to the rollers, again to perform its task. While returning to the roller, the thread which has been spun is wound or built on the spindle in a conical form, and is called a cop. The mule-jenny has become a 'self-acting machine,' by some beautiful inventions of Messrs. Sharp and Roberts, at Manchester. Some of the modern double self-acting mules contain 2200 spindles, all managed by one man.

The spun yarn is reeled into hanks containing 840 yards. Yarn of *low* numbers, or below 40 hanks to the lb., is generally spun by the throstle; but *high* numbers, or fine yarn, is more frequently spun by the mule. At Houldsworth's Mill, at Manchester, yarn was spun a few years ago to the astonishing degree of fineness of No. 460; that is, 460 × by 840, or 386,400 yards, or nearly 220 miles in length, from 1 lb. of cotton. This yarn was worth five times its weight in silver, and was spun for a muslin dress for her Majesty. But even this triumph of skill is about to be exceeded. A Manchester manufacturer is spinning a pound of cotton for the Great Exhibition of 1851, in length 238 miles and 1120 yards, being the finest ever yet produced. Those most conversant with the details of cotton-spinning can best appreciate the value of the machinery and the talent displayed in so wonderful a production. The cotton was, we believe, from Egypt, and is considered the finest specimen that was ever imported into this country.

COTTON or CALICO PRINTING. This art has been practised from time immemorial in India. Pliny describes a mode which was adopted by the Egyptians in staining cotton cloth, evidently similar to the modern process of employing wood-cuts. In India, not only is the art of using wood printing-blocks well known, but also that of applying resist-pastes, in order to preserve the cloth from the action of the dye-bath in any desired figures or spots. Processes of printing, similar to the Indian, have been long practised in Asia Minor and in the Levant; but they were not attempted in Europe till about the middle of the 17th century. The first print-ground in England was established near Richmond, in Surrey, in 1696; but it was not till the year 1768 that the business was carried into Lancashire, where it now constitutes one of the most interesting and productive branches of English manufactures. From its outset the printing of cotton goods encountered the keenest hostility from the silk weavers of Spitalfields; and it was not till 1831 that printed cottons were relieved from the burdens thrown on them by protection.

Calicoes, muslins, &c., intended for printing are first of all freed from their fibrous down by the action of the *singeing machine*. This consists either of a semi-cylinder of iron or copper, laid horizontally, and kept at a bright red heat by a furnace, or by a horizontal range of gas-jet flames: over one of these the plain of cloth is drawn with a steady continuous motion, and at a rate suited to its texture. The cotton cloth is next well bleached [BLEACHING], because, the whiter it is, the more light it will reflect from its surface, and the more brilliant will be the colour of its dyes. The goods are next rinsed, dried, and sometimes smoothed under the calender. If they are not calendered, they are run through a machine called in Lancashire the *candroy*, which spreads them smoothly in the act of rolling them upon a cylinder.

There are four mechanical modes of printing calicoes: first, by small wooden blocks, worked by hand; second, by large wooden blocks, set in a frame, and worked by a machine called the *Perrotine;* third, by flat copper plates (a method now nearly obsolete); and fourth, by copper cylinders.

The blocks are made of sycamore wood, or of deal faced with sycamore. They are about ten inches long and five broad, with an arched handle on the back for convenience of holding. The face is either cut in relief into the design required, or the same object is obtained by the insertion edgewise into the wood of narrow slips of flattened copper wire in the desired configurations. These narrow fillets have one edge inserted into the wood, are fixed by the taps of a light hammer, and are all filed down and polished into one horizontal plain, to secure equality of impression in the several lines. The interstices between the copper ridges are filled up with felt-stuff. Occasionally both the wood-cutting and insertion plan are combined in one block.

Calico-printing by hand is performed by applying the face of the block to a piece of woollen cloth stretched over one end of a sieve-hoop, and imbued with a colouring matter of a thin pasty consistence by means of a flat brush. The block is then applied to the surface of the cotton cloth while extended upon a flat table covered with a blanket, and the impression is transferred to it by striking the back of the block with a light mallet. This method, besides the great cost of labour which it involves, has the inconvenience of causing many irregularities in the execution of the work. It has been superseded to a considerable extent, both in France and Belgium, by the Perrotine. Three thin wooden blocks, engraved in relief, about three feet long, and from two to five inches broad, are successively brought to bear on three of the four faces of a prismatic roller of iron, round which the cloth is successively wound. Each block rests on springs, which enable it to press with the delicacy of a skilful arm; and each receives its peculiar-coloured paste from a woollen surface imbued by a mechanical brush in rapid alternation. In England a machine has been introduced in which three or more oblong blocks are laid side by side, and are imbued with different colours all at the same time, from a trough arranged for the purpose.

The *cylinder-machine* consists of a hollow cylinder of copper about three feet long and three or four inches in diameter, whose surface is engraved, not by the hand-graver, but by the mechanical pressure of a steel roller from one to two inches in diameter, and three inches long, which transfers the figures engraved on it to the relatively softer copper. The first steel roller, called the die, is softened before being engraved in intaglio; it is then hardened, and made, by a powerful press, to transfer its design in relief to a similar die called the mill, which is the one used for transferring the design to the copper cylinder. The process of etching is also sometimes had recourse to for covering the cylinder with various figures.

The engraved cylinders are mounted upon a strong iron shaft or arbor, carrying a toothed wheel at its end, in order to put it in train with the rotatory printing machine, for one, two, or more colours. On a roller, at the upper part of this apparatus, are wound whole calico webs stitched together, the end of which is then introduced between the engraved copper cylinder and a large central cylinder covered with blanket, against which it is made to bear with regulated pressure. The engraved cylinder turns on the top of another cylinder covered with woollen cloth, which revolves with the former while its under part is plunged in an oblong trough containing the dyeing matter, which is of a pasty consistence. The engraved cylinder is thus supplied with an abundance of impressible colour, and is cleared from the superfluity by the thin edge of a flat ruler made of bronze, called vulgarly the doctor, which is applied obliquely to it with a gentle force. The cylinder, after its escape from this wiping tool, acts upon the calico, and rolls it onwards with its revolution, imparting its figured design with great precision. One single machine will print calico at the rate of a mile an hour.

Dye-stuffs, capable alone of imparting fast colours to calico, have been called *substantive;* and such as require the intervention of a mordant, *adjective.* Indigo, catechu, and certain metallic oxides belong to the former class; madder, cochineal, and Persian berries to the latter. There are five general styles of work in calico printing:—1, The fast colour or chintz style, in which the mordants are applied to the white cloth, and the colours of the design are afterwards brought up in the dye-bath. 2, Where the whole surface receives a uniform tint from one colouring matter, and figures of other colours are afterwards brought up by chemical discharges and reactions; this is called the Rongeant style in France. 3, Where the white surface is impressed with figures in a resist-paste, and is afterwards subjected to a general dye, such as the indigo-vat. 4, Steam-colours, in which a mixture of the mordants and dye-extracts is applied to the cloth, and the chemical combination is effected by the agency of steam. 5, Spirit-colours, consisting of mixtures of dye-extracts with nitro-muriate of tin; these cannot be exposed to a steam heat without corroding the cloth: this style is brilliant, but fugitive.

The tint or shade of colour produced in the dyeing-bath is proportional to the strength of the mordant previously applied to the cloth. The thickening of mordants is one of the most important operations in calico-printing; for the permanence and beauty of the impression depend not a little on the consistence and quality of the inspissating substance. The substances usually employed in thickening are flour starch; flour; roasted starch; gum Senegal; gum tragacansh; salep; pipe-clay mixed with gum Senegal; potato starch; sulphate of lead and gum; sugar; treacle; glue.

In the printing of yellows, greens, purples, pinks, and browns, different colouring substances are used, and different processes adopted for causing the colours to combine permanently with the cloth; but they all possess a common character, inasmuch as mordants are applied to the white cloth, and the colours of the design are afterwards brought up in the dye-bath.

In almost all the modes of calico-printing, the processes are very numerous, to ensure the beauty and the permanence of the colours. In what is called the *steam-colour* printing, the agency of steam is applied to aid in fixing the colours to the cloth. The cloth is first steeped in a mordant liquor; then printed by the cylinder with various colours, which for their peculiar properties are called steam-colours. The cloth is hung up to dry, and when dry it is exposed to the action of dry steam. This is done by five different kinds of apparatus—the column, the lantern, the cask, the steam-chest, and the chamber. The first of these, which is most frequently used, is a hollow copper cylinder about 45 inches long by 2 to 6 in diameter, perforated along its whole surface with small holes one quarter of an inch apart. To the lower end of the column a circular plate is soldered, which serves to prevent the cloth coiled round the cylinder from falling down from it. The bottom of the hollow cylinder is terminated by a tube one inch wide, which fits tight into the socket of an iron chest beneath it, into whose side the steam pipe of supply enters. The goods printed with the steam-colours and properly dried are lapped tight round this hollow cylinder, and covered exteriorly with an envelope of strong cotton cloth, blanket-stuff, or flannel. The steam is then let on, and continued for 20 or 30 minutes, according to the nature of the dyes. The steam being stopped, the printed goods are rapidly unrolled from the column while still hot, lest any condensation of vapour should take place to stain them.

A pretty and ingenious method of producing the 'rainbow' pattern is as follows: a number of sieves, containing the different shades of colour, are placed nearly under each other, over each sieve a disc revolves, having projections of copper wire, which dip into the colours. These discs are supported on pedestals which admit of easy adjustment, and are so regulated, that as they revolve the projecting wires give colour to the cylinder in successively lighter shades.

The designs for calico printing are very costly. A copper cylinder is worth from 5*l.* to 7*l.*; and the engraving costs from 5*l.* to 10*l.* more. A constant succession of new patterns must be kept up by the manufacturer to produce 'novelties' for the season. Some of the Lancashire firms expend as much as 5000*l.* a year in designing and engraving new patterns. Property in these designs is secured by law. [Designs, Copyright, and Registration.] The art of designing now receives encouragement from the government. [Design, Schools of.]

In the year ending June 1846, the printed and dyed cotton goods exported from this country amounted to 327,465,580 yards.

COUNTERPOISE is, generally, a mass of brass or iron so disposed as to keep a part of some instrument or machine in equilibrio. Large astronomical instruments are generally mounted so that their centres of gravity are supported, in which case they require no counterpoise; but a reflecting circle is sometimes so placed as to require a heavy counterpoise on the other side of the pillar which sustains it. A transit instrument or mural circle, whose pivots would press heavily on their supports, is sometimes provided with counterpoises, one for each point which is to be relieved. Lord Rosse's great telescope has two counterpoises to assist in the requisite adjustments. A drawbridge usually has its weight relieved, or almost wholly removed, by a counterpoise, so that the machinery employed to raise it has little except the resistance arising from friction to overcome.

COUPLING, in machinery, is the name given to various arrangements by which the parts of a machine may be connected or disconnected at pleasure, or by which a machine may be disengaged from, or re-engaged with, a revolving wheel or shaft, through which it receives motion from a steam-engine, water-wheel, or other prime mover. Coupling-boxes, clutches or glands, a solid conical wheel working in a hollow cone, friction-wheels whose peripheries act in contact, and Hook's universal joint, are different forms of apparatus for effecting this adjustment.

COURTRAI, a town in West Flanders, is famous for the manufacture of damask and other linen textures, which are exported to all parts of Europe. Flax of the finest quality is produced in large quantities in the vicinity, which contains a great number of bleaching establishments, The dyers of Courtray imitate with success the colour known as Turkey red. Thread and silk lace are among the branches of industry pursued.

COVENTRY. In the time of the Edwards and Henries, the tradesmen of Coventry were famed for their affluence. In 1448 they equipped 600 armed men for the public service. Until the war between England and France in 1694, the staple manufacture was woollens, broad-cloths and caps; and previous to 1580 there existed a famous manufacture of blue thread; the water of the small river Sherbourne, which passes through the city, being an excellent menstruum for dyeing this colour. During the 18th century there was a flourishing manufacture of tammies, camlets, shalloons, calimancoes, gauzes, &c., but it is no longer continued. At present the staple manufactures are ribbons and watches. The ribbon manufacture was introduced about 1730, and is supposed now to give employment to about 6,000 persons in the city; it is said that 20,000 are employed in ribbon weaving in Coventry and the vicinity. The weaving has hitherto been almost entirely performed by the hand-loom, and the weavers are in general a poor class; but steam factories have been of late increasing, and are probably superseding the loom at the workmen's dwellings. The leaders of the trade are not the manufacturers, but a comparatively small number of wholesale firms in London and Manchester, whose agents attend at Coventry. Gimp and other trimmings are also made in Coventry, and there are large establishments for dyeing silk. The making of watches has been carried on here probably as long as the ribbon manufacture, and is now so extensive that as many watches are said to be made in Coventry as in London.

The Report on the Government Schools of Design for 1850 contains a statement relating to the branch school of Coventry well worthy of attention. 'Of the beneficial influence of the school on the manufactures of the town, the manufacturers entertain a strong and increasing conviction; for the employment of designers in the strict sense of the term, the ribbon manufacture affords but a narrow basis; and until the prejudices of the public in favour of French ribbons is removed, there can be but little production in England of that description of goods upon which designs of the highest class can be exhibited; but it is certain that during the last five years there has been a marked improvement in the Coventry patterns, accompanied by improved quality and closeness of texture in the fabric, and that a superior class of Coventry goods, to some extent, under the name of French, is gaining ground in the market. These results the manufacturers unhesitatingly ascribe to the superiority which the rising generation of pattern draughters have attained through their education in the school. Nor is it only in the greater refinement and better execution of the patterns that an advantage has been obtained; they are also drawn and draughted at a much less expense than formerly, an evidence that it is the young hands and apprentices who excel in the art.'

There are several guilds, or incorporated trading companies, some of which are possessed of considerable property, which they spend in charity and festivities.

The local position of Coventry is favourable for commercial operations, being nearly central between the four greatest ports of England—London, Bristol, Liverpool, and Hull; possessing great facilities of water communication by the Coventry and Oxford Canal, which opens into the Grand Trunk navigation, and having one of the main roads from London to Birmingham passing through its streets. The London and North Western Railway passes close to the town; and there are two branch lines, one turning northward to Leamington and Warwick, and another (not yet finished) to Nuneaton.

COWRY SHELLS are called by conchologists *Cypræa*. Their beauty has procured them a place among the ornaments of our chimney-pieces, and they have been in demand among civilised and uncivilised nations time out of memory. Cowries are used as small coin in many parts of Southern Asia, as in India, the Burmese Empire, Siam, &c., and especially on the coast of Guinea in Africa. In 1740 a rupee in Bengal was worth 2400 cowries; in 1766, 2560 cowries; and now, we believe, 3200 may be had for it.

COYPOU or COYPU is one of the numerous fur-bearing animals of South America. Like the beaver it has two kinds of fur; an outer coat of long ruddy hairs, and an under garment of fine brownish wool, much used in the manufacture of hats. In France the skins of this animal are sold under the name of Racoonda. M. Geoffroy mentions that in certain years a single French furrier, M. Bechem, has received from 15,000 to 20,000 skins. They are imported into Great Britain to a large amount; from 600,000 to 800,000 have been stated as the importation of one year, principally from the Rio de la Plata. They are here known under the name of Neutria or Nutria, an appellation derived from some supposed similarity in the habits and appearance of the animal to those of the otter, the Spanish name of which is Nutria.

CRAB is a kind of portable windlass, or machine for raising weights, or otherwise exerting force, by winding a rope or chain round a horizontal barrel. Crabs are usually mounted in a strong heavy framework of wood or iron; and, when employed for a temporary purpose, but one which involves considerable strain, they are either bolted down to a temporary foundation, or loaded with heavy weights put upon the framework.

CRACOW. The little which can be said concerning the produce and industry of Cracow will be found under POLAND.

CRADLING, is a name given to the slight timber-framing constructed under floors in order to form arched or coved ceilings.

CRAMP, or CRAMPERN, is a piece of metal bent at each end and let into the upper surface of two pieces of stone when their perpendicular faces are joined together. Cramps are employed in the masonry of all solid structures. Iron is mostly used, but copper is more durable. The Greeks used cramps in the construction of their temples, and wooden cramps were sometimes used by the Egyptians.

CRANE, is a machine employed for raising weights vertically by means of a rope or chain acted upon by a windlass, but carried over a pulley or wheels attached to the extremity of a projecting arm or jib. The common warehouse crane, which is usually formed of iron, may be compared to an inverted L, the vertical portion of which is so mounted as to form a pivot or axis upon which the whole may be swung round; so that the horizontal arm, which is strengthed by diagonal struts, may extend in any direction. The rope or chain of such a crane is conducted along the horizontal arm, and connected with a kind of windlass or crab, which is usually provided with two sets of gearing for working at different velocities, so that in raising light goods a much greater speed may be given to the chain with the same motion of the winch-handles than when the load is very heavy. Wharf-cranes are frequently of somewhat different construction, owing to the circumstance that they usually stand alone, that is to say, that they are self-supported, instead of being attached to and supported by a wall or a post secured to a wall. There is a vertical pillar of iron or wood, the lower end of which is firmly secured to a foundation of masonry, while the upper end terminates in a pointed or conical pin, upon which, as a pivot, the revolving part of the crane rests and turns. The arm or jib projects obliquely from the pillar, and is strengthened by diagonal braces. The windlass or crab for working the crane is attached to the central pillar. Some cranes are worked by a tread-mill moved by men; some by horses or oxen; some by the surplus power of a steam engine; some by the compression of air in a strong vessel; some by hydrostatic pressure; but the customary mode is by a winch-handle. Many of the cranes at the principal docks and quays are capable of raising immense weights.

Mr. W. G. Amstrong, who has introduced many ingenious applications of water power, has recently patented a singular method of working a crane by means of the pressure of the water in the common water pipes of a town. One such hydraulic crane was set up and worked on the quay at Newcastle in 1846. The machinery for working the crane is all underground. There is a sort of dial plate visible, with handles or indicators for guiding all the movements of the machine, such as raising, lowering, stopping, &c.; these indicators act upon valves which regulate the water-pressure beneath, so that the movements produced can be made exactly proportionate to the work to be done.

Mr. Henderson's derrick crane, which has been so largely used by Messrs. Fox and Henderson at the Industrial Palace in Hyde Park, is especially adapted for circumstances where the crane is required to be moved from place to place during the progress of the works. This kind of crane has a derrick or jib, rising nearly from the ground, and hinged at its lower extremity to the upright post of the crane. This hinge enables the derrick to be moved to any required angle, so that the upper extremity may be near or far from the central post, according to the position of the load to be raised. While the derrick can thus move vertically on a horizontal hinge, the post can rotate horizontally on a vertical pivot; so that the crane has a wide extended area of action.

CRANK, in machinery, is a bend in an axle by which a reciprocating motion in a rod is made to produce a revolving motion of the axle and of a wheel which may be connected with it.

CRAPE is a light transparent fabric composed of silk, from which, by the mode of its preparation, all the gloss has been taken, and which, when dyed, as it usually is, of a black colour, is worn as a material for mourning-dresses. For thin crape, the only preparation which the filaments of silk undergo previous to the weaving is the simple twisting, which forms the first process of the throwing mill, and in which state the thread is technically called *singles.* When it is intended to make a more substantial fabric, the warp is made of two and sometimes three filaments twisted together, which in that state are called *tram:* the weft is still composed of singles. The wrinkled appearance of crape is produced by the application of a viscid solution of gum.

In the Custom House returns, crape goods are entered distinct from other varieties of silk. In 1848 crape shawls, scarfs, and handkerchiefs were imported to the value of 15,490*l.*; partly from France, but chiefly from India.

CRAYONS are a useful kind of material for drawing. Black chalk found in Italy, white chalk found in France, and red chalk, form three of the best varieties of crayons; each has its own peculiar value as a drawing material. Artificial crayons are composed of different coloured earths and other pigments, rolled into solid sticks with some tenacious stuff such as milk, common gin, or beer wort; the best are procured from Switzerland. A new kind called Athenian crayons has recently been introduced; they are sold at the London colour-shops at three to four shillings per dozen. The native crayons are the legitimate materials for the artist in the study of drawing, and in tracing the first thoughts of design. Some of the sketches of Raphel, Michael Angelo, the Caracci, and others of the great painters are in this material.

An instrument called a portcrayon is employed to hold the crayon. It is a metal tube split at each end, so as to admit the crayon; a sliding ring embraces the tube, and assists in retaining the crayon. A stump made of leather, cork, or paper, closely rolled, or cut into a short round stick more or less sharply pointed at each end, is used to soften and spread the chalk or crayon in the shaded parts of the drawing.

Messrs. Wolff have recently introduced what they call crayon-paper; its surface has a fine nap similar to that of cloth, which renders it capable of receiving the marks of the crayon with great readiness.

The following materials are said to form a kind of crayon fitted for drawing on glass. Equal quantities of asphaltum and yellow wax, melted together, thickened with lamp black, and poured into moulds to form crayons. These crayons may be bevelled to a fine point, and will mark well on a perfectly clean piece of glass.

CREAM. [BUTTER; MILK.]

There are various preparations which pass by the name of *creams*, and which for the most part consist of cream combined with syrups, spices, fruits, &c.; but sometimes there is no milk-cream contained in them; the name being derived from the consistency rather than from the ingredient.

The French *crémes* are cordials or liqueurs, which have a cream-like smoothness in their taste. Such are the Créme d'Anise, Créme d'Orange, &c.

CREASOTE or KREASOTE is a fluid compound of oxygen, hydrogen, and carbon, obtained from oil of tar. It is colourless, transparent, and has a strong odour which greatly resembles that of smoked meat, with a caustic and burning taste. It is highly antiseptic, and combines both with acids and with alkalies; but it is decomposed by strong nitric and sulphuric acid.

Creasote coagulates albumen, even when much diluted, and it also coagulates serum. Meat and fish are preserved after having been brushed over with creasote and dried in the sun; the antiseptic power of pyroligneous acid and wood smoke is supposed to be derived from its presence. A few drops added to ink are said effectually to prevent its becoming mouldy.

Creasote, from its extraordinary antiseptic qualities, is becoming employed in various ways for the preservation of animal and vegetable food. A joint of uncooked meat, in hot weather, may be preserved pure for many days by the use of this remarkable agent. There are many ways in which this may be done. The meat may be exposed to the smoke produced by the burning of the wood which contains or yields creasote; or the meat may be soaked for a short time in water which contains a few drops of creasote; or it may be hung up in a larder or safe, with a dish beneath it containing a little creasote, the slow evaporation of which gradually affects the meat. The first two of these methods are in some respects objectionable, inasmuch as a peculiar smell and taste are imparted to the meat; but in the third method, especially if both the dish and the meat are covered with cloths, the antiseptic effect is said to be produced without the accompaniment of the odour and taste.

CREDITON. On the rise of the woollen manufacture in the west of England, Crediton became one of the most important seats of that branch of industry. Little cloth is now made in the town; but hand-loom weavers are employed in their own houses by manufacturers at Exeter and North Tawton. The principal occupation in the town at present is shoe-making, which employs several hundred people. At Fordton, south of the town, is a manufactory for coarse linens, dowlasses, sail-cloth, &c. Early in 1848 a railway was completed from Exeter to Crediton, and it was about to be opened in connection with the Great Western Railway, when the South Western Company obtained a majority in the direction, and altered it from the broad to the narrow guage, with a view to open it in connection with a projected line from Exeter to Yeovil and Salisbury. This led to litigation, and the consequence has been that the Crediton railway has not been opened to the present time (February 1851).

CREFELD, a town in Rhenish Prussia, is a place of great manufacturing activity; the principal fabrics are silks and velvets, which are woven chiefly by hand, and give employment to 6000 workpeople. The articles of manufacture are calicoes, woollens, tape, ribands, linen, hosiery, glass, refined sugar, soap, iron, and cotton wares, &c.

CREMONA. The produce and industry of this beautiful city and district are similar to those of the country in which they are situated. [LOMBARDY.]

CRETA LEVIS. This name has been recently given to a kind of drawing pencils, intermediate in character between lead pencils and crayons. Being formed of very fine chalk, they somewhat resemble crayons; but they are put into handles or hollowed sticks like pencils. The pencils can be cut to a fine point; and as they are made of every variety of colour, they form a convenient means of imitating, in a rough but expeditious way, the effects of a water-colour drawing. They are sold at six to twelve shillings per dozen according to the colours.

CREWE, in Cheshire, is one of the most remarkable instances of a thriving and populous town springing into existence in connection with the system of railway communication. It owes its erection entirely to the formation of the London and North Western line of railway. The inhabitants consist almost wholly of persons in the employment of the railway company, with their families, and the tradesmen and shopkeepers required to supply them with the necessaries and conveniences of life. The houses and shops in the town are, of course, nearly all new, and they are well built; the streets are wide, and the footpaths are laid with asphalte. The town is lighted with gas, and well supplied with water; a powerful steam-pump supplying at once the engines in the extensive workshops of the company, the locomotive engines, and the houses in the town. This pump raises from 80,000 to 90,000 gallons of water daily; the portion intended to be used by the inhabitants passes through two filtering processes before reaching the houses. Baths are also provided at a cheap rate. The town of Crewe has a council for the management of the affairs of the community: two-thirds of the council are elected by the workmen and inhabitants, and one-third by the directors of the railway company. Medical attendance and medicine are secured for the workmen and their families on payment of a small weekly rate, the highest charge (that for a married man with a family) being 2*d.* per week. A field in the neighbourhood is used for cricket-playing.

The railway station at Crewe is very spacious and splendid. From this place branch off five lines of railway, affording ready means of communication with all parts of the country. The workshops and machinery of the North Western Railway Company at Crewe are on a very extensive scale. Railway carriages and locomotive engines are manufactured and repaired. The number of carriages of all kinds maintained at Crewe amounts to nearly 700, of which 100 at a time are usually under repair.

CRIMPING MACHINE. Hughes's crimping machine, patented in 1844, is intended to produce all those varied forms in woven goods called crimping, fluting, quilling, and goffering, for ruffs or *rouches*. A female worker employed at this process can goffer about 288 yards of blonde in twelve hours; the new machine will do about eight times that quantity in the same time. The machine consists essentially of a series of rods, laid parallel, and revolving on their axes in contact with one another. The muslin or other material is drawn between the rods, and receives in its passage a series of flutings or other wavy forms, the precise arrangement of which depends on the shape and arrangement of the rods. The machine acts on a principle nearly analogous to that employed in many departments of the sheet metal manufacture; such, for example, as the preparation of corrugated sheet iron for roofs.

CRINAN CANAL, in Argyleshire, was constructed for the purpose of enabling vessels of small burden to dispense with the rather dangerous passage round the Mull of Cantyre, from Lochfyne to the Sound of Jura. The project of forming this canal was first started about 60 years back under the auspices of the then Duke of Argyle. Sir John Rennie, the civil engineer, having surveyed the ground and reported favourably, an act of parliament was obtained, and a company formed in 1793, and the works were forthwith commenced. The canal was opened in 1801. Engineering difficulties in constructing the works, and alterations in the original plans, added considerably to the estimated expense, and parliamentary grants have been more than once made in aid of the company. The canal, although not more than 9 miles in length, has been of great service to the coasting trade of the west of Scotland and the Highlands. The number of locks in the Crinan Canal is 15; the average breadth is 24 feet, and the depth of water 10 feet: if found necessary, 12 feet depth of water could be maintained. Since 1818 the canal has been under the management of the Commissioners of the Caledonian Canal, with the navigation of which it is intimately connected; together these canals form an important portion of the inland passage between Glasgow and Inverness. In 1848 the dues on vessels and merchandise were somewhat reduced, and an increase of traffic is anticipated. Vessels of 200 tons burden can pass through the canal.

CROCKET, is an ornament of frequent use in Gothic architecture. It consists of leafy buds growing out of the angular sides of pinnacles and the label moulding of windows and doors.

CRONSTADT, or KRONSTADT. There are two important commercial towns of this name, one in Transylvania and the other in Russia. Cronstadt in Transylvania manufactures cloth, linens, cottons, coarse woollens, hosiery, woollen yarn, &c., flasks of maple wood, &c. There is a paper-mill, and two grounds for bleaching wax. Cronstadt was the first place in Transylvania where a printing-press was established. The town has a very important commerce in manufactured goods, Austrian and Turkish produce, salt, &c., which is chiefly in the hands of a Greek trading company.

Cronstadt in Russia is the harbour of St. Petersburg, and the principal naval station of Russia. There are three harbours, one of which, capable of containing 600 ships, is allotted to merchantmen. The imperial naval harbour is formed by a mole, and can accommodate 35 ships of the line besides smaller vessels. Adjacent to it are slips for building ships, a powder magazine, a manufactory of pitch, tar, &c. Vessels are repaired and built in the large canal of Peter the Great, which runs directly into the town between the middle and merchant's harbour. Near it are the various docks for repairing ships; the foundry, which supplies annually 1200 tons of bombs, balls, &c.; the admiralty rope walk, tar works, and excellent wet docks. By the Catherine Canal vessels are enabled to take their stores, munition, &c., directly from the store houses. Large vessels load and unload at Cronstadt, and the cargoes are conveyed to and from St. Petersburg by lighters; but vessels drawing not more than 8½ feet water can get over the bar of the Neva.

CROTON AQUEDUCT. [AQUEDUCT.]

CROTON, is the name of a plant which is largely used in medicine. Cascarilla bark is yielded by the *Croton cascarilla*, a tree or shrub growing in the vicinity of Jalapa. It occurs in pieces about a foot long. The colour externally is yellowish, ash-gray, or varying to reddish brown: this last colour is mostly owing to the presence of lichens. The inner surface is a dirty or rusty brown colour. The odour is faintly aromatic: taste bitter, not unpleasant, and stimulating. One pound of bark yields one drachm and a half of volatile oil. This bark is sometimes mixed with cinchona barks, being called *Gray Fever Bark. Croton tiglium*, an inhabitant of the Moluccas, Ceylon, and other parts of the East Indies, is a powerful drug; every part, wood, leaves, and fruit, seems to participate equally in the energy. The *Molucca grains*, formerly used in medicine, were the seeds of this species. *Croton lacciferum* is a native of the East Indies. This species is said to furnish the finest of all the sorts of lac, but scarcely ever to find its way to England; it is very pure, of a bright red, and furnishes a brilliant varnish in Ceylon. From the *Croton balsamiferum*, the liqueur called *Eau de Mantes* is distilled.

CRUCIBLE, is a chemical vessel in which substances are exposed to high temperatures. Earthen crucibles are used in assaying ores: for these purposes the refractory kind, called Hessian or Cornish crucibles, are prepared. Black lead crucibles, formed of about three parts of plumbago and one of good clay, are much employed, especially in melting metals. Glass-makers' crucibles are usually made of Stourbridge clay. Crucibles of silver and of platinum are employed in various chemical processes.

CRUTH, or CRWTH, a musical instrument of the violin kind, was formerly much used in Wales. It had six strings and was somewhat of the lute form.

CRYO'PHORUS. Dr. Wollaston gave this name to an instrument invented for the purpose of exhibiting the congelation of water in consequence of evaporation. It consists of two glass bulbs connected by a bent stem. One of the bulbs, if cooled when empty, causes water to freeze in the other, the stem being in vacuo.

CRYPT, is the name given by architects to a low-vaulted chamber, the vaulting of which is supported on columns and the basement walls of a church or cathedral. Some crypts have become the receptacle of the monuments of the dead, as at the abbey of St. Denis. Crypts are far from being common to all churches and cathedrals.

CRYSTALS; CRYSTALLOGRAPHY. Although the study of crystals as a science, apart from their practical applications in the arts, does not belong to the present work, it may be useful to explain certain terms and properties, which are constantly in use when crystals are spoken of. Mineralogists have adopted certain groups of *primary* and *secondary* forms, as a means of classifying crystals. The primary forms, according to one system of crystallography (for there are more systems than one), consist of the *cube*, the *square prism*, the *right rhombic prism*, the *oblique rhombic prism*, the *doubly oblique prism*, and the *rhomboid* or *rhombohedron*. The nature of these forms may be best explained by showing the relations between them. The *cube* has the well-known form of a die, with six equal surfaces. If the lateral edges of the cube be supposed to be longer or shorter than the terminal edges, a *square prism* would be produced; if two opposite lateral edges of a square prism could be pressed towards each other, the parallelism being kept, a *right rhombic prism* would be formed; if this prism could be pressed in the direction of either of the diagonals of its terminal plane, so as to make the figure overhang the base in that direction, an *oblique rhombic prism* would be represented; and if again pressed in the direction of the other diagonal, so that it should overhang the base in both directions, a *doubly oblique prism* would be formed. If a cube be made to stand on one of its angles by placing the fingers on an opposite one, and if, while held in this position, the two angles could be pressed nearer together or drawn further apart, the altered cube would become a *rhomboid.*

The *secondary* forms of crystals are supposed to be occasioned by some natural influence operating upon the first germ of the crystal, and continuing during the period of its increase in size. The number of known secondary forms belonging to each system is already very great; in one mineral, carbonate of lime, they amount to many hundreds. Crystals occur more frequently in the secondary than the primary forms. *Twin crystals* are produced by the union of two or more crystals according to some regular plan, so that, if any number of twin crystals of the same kind of mineral should be found they would be fashioned in the same manner.

The crystallisation of salts from solution in fluids generally takes place when the solutions are considerably evaporated, but the degree of evaporation is very different for different substances. Some salts begin to crystallise at the surface very soon after evaporation commences; and others (for example sugar) must be evaporated to the consistence of a thick syrup before any crystals will be formed. Hot fluids will generally dissolve more matter than cold ones, and crystals are frequently produced during the cooling of the hot solution. Some soluble substances however cannot be brought to crystallise under any circumstances hitherto tried; but, on the solvent evaporating, a thick pasty matter is left, which by further evaporation becomes a hard solid mass. Camphor affords an instance of the formation of crystals by volatilization. The slags of furnaces will frequently be found to contain crystallised matter; and the common rolls of sulphur when broken will frequently present small cavities lined with thin needle-like crystals. Becquerel, Crosse, Fox, and others, by the electrical induction of chemical action, have effected the crystallisation of mineral bodies which are wholly insoluble in any fluid which does not subject them to immediate chemical change.

CUBA is the largest of the islands which constitute the Columbian Archipelago, in the foreign West Indies. The objects raised for consumption and exportation are sugar, coffee, tobacco, cotton, cocoa, and indigo; but the last three on a very small scale. As immense tracts are not cultivated, but only used as pasture ground, the number of cattle is very great, and hides form an article of exportation. About 2,000,000 acres, or one-fourteenth of the whole surface of the island, is under cultivation. The uncultivated part contains large prairies of great fertility, on which great numbers of cattle pasture; but the greatest part is overgrown with large forest-trees, some of which supply excellent timber for ship-building. Gold and copper have been found in the Sierra del Cobre.

In few countries has commerce increased so rapidly as in Cuba. About 1780 the exportation of its own produce amounted to little more than two millions of Spanish dollars in value: in 1760 the produce of sugar and coffee together amounted to 5,000,000 lbs.; in 1800, to above 40,000,000 lbs. In 1820 the exports of these articles reached 100,000,000 lbs.; and in 1847 the quantity of sugar alone exported had advanced to 256,800 tons, or 575,232,000 lbs. In 1842 the exports of Cuba amounted to 26,000,000 dollars. Havana is by far the largest port for foreign trade. The chief articles of importation are provisions, particularly flour, rice, and maize, butter, cheese, candles, tallow, jerked beef and hams, and salted fish and cod. Brandy and the wines of Spain, France, Portugal, and Germany, also form a considerable branch of importation. As Cuba has no manufactures, cotton stuffs, woollen goods, linens, hardwares, and silk stuffs, are imported to a large amount. Of the whole exports, rather more than one-third are to England, and one-fifth to the United States. Of the whole imports about one-eighth are from England, and one-fourth from the United States. The recent change in the sugar duties has largely increased the English consumption of Cuba sugar.

The exports from Great Britain to Cuba, in 1848, amounted in value to 733,169*l.* The chief items were:—

	£
Brass and copper manufactures	19,452
Coals	14,469
Cotton manufactures	228,986
Earthenware	24,411
Hardware and cutlery	38,578
Iron and steel goods	83,250
Linen manufactures	218,121
Woollen manufactures	41,207

Among the articles imported from Cuba in 1848 were:—

Coffee	586,250 lbs.
Molasses	42,511 cwts.
Rum	158,817 gals.
Sugar	734,862 cwts.
Tobacco	512,984 lbs.

The internal traffic, formerly impeded by the badness of the roads, is much facilitated by the introduction of railroads, of which there were 800 miles open in 1847; the coasting-

KNIGHT'S CYCLOPÆDIA OF THE INDUSTRY OF ALL NATIONS.

trade is active, 4,000 small vessels being used to bring the produce of the neighbourhood to Havana alone.

CUDDAPAH DIAMONDS. [Diamond.]

CUIRASS or CUIRASSE. The cuirass, in former days, was a piece of defensive armour, made of metal, and serving to cover the body from the neck to the girdle, both before and behind; the front, called the breast-plate, and the hinder part or back plate were fastened to each other by straps, buckles, hooks, or some other contrivance. The Egyptians are said to have been the inventors of such armour, but among that people it consisted of folds of linen. Cuirasses of brass or steel, and occasionally of gold or silver highly ornamented, were used by the Greeks and Romans. After having been long disused, the cuirass was revived in Europe about the middle of the fourteenth century. In the Mediæval Exhibition of 1850 many curious specimens of these old cuirasses were collected. In the English service the cuirass was again disused after the reign of George II. Since the year 1820, however, it has been revived as part of the accoutrements of the life-guards.

CULTIVATOR. The names of *Cultivator* and *Scarifier* are sometimes given to an agricultural machine on three wheels, which has five arms or vertical bars, the lower ends of which are shaped something like ploughshares. These points or rather blades project forward, and act to a slight depth upon the earth as the machine proceeds. They are adapted for strong retentive clay soils. A Cultivator was exhibited at the Smithfield Cattle Show, 1850, by Mr. Smith of Uxbridge; similar in principle to some now in use at the royal farms in Windsor Forest.

Harris's Annular Cultivator, registered in 1850, has seven shares or cutters ranged round a circle, intended to ensure a more equable action on the soil than when they are arranged in right lines

CUMBERLAND. This county is rich in minerals; comprising silver, copper, lead, iron, plumbago, limestone, and coal. The principal lead mines are situated at Alston, and are almost exclusively the property of Greenwich Hospital, to which institution they were appropriated by act of parliament on the attainder of the Earl of Derwentwater. Silver and copper are found in some of the mines in the same veins with the lead ore. Silver and lead are got in abundance at Greenside and Eagle-crag in Patterdale. Veins of lead-ore have been found and worked between Skiddaw and Saddleback, in Buttermere, Newlands, and Thornthwaite. There are copper mines at Alston, Caldbeck, and at Wythburn. There is one also below the level of Derwent-water, and another in the parish of Lowes-water. A very rich vein of gold is said to have been discovered at Newlands by a German, in the time of Queen Elizabeth; but the working was discontinued in consequence of a law-suit between that queen and the Earl of Northumberland, then the lord of the manor of Derwent-fells. Iron-ore is raised in great abundance near Egremont; the thickness of the band of ore, which is hard solid metal, is said to be between twenty-four and twenty-five feet. The quantity of iron ore shipped from Ulverston and Barrow is very great: 300 carts of ore are taken daily from Lindale to Barrow for exportation. The ore of this county produces upwards of double the quantity of metal that is got from iron ore in general; and it is often mixed in the smelting furnaces with the South Wales ore to produce a particular quality of iron. Coal is worked to a large amount at Whitehaven, Workington, and in the vicinity of Maryport, from whence it is exported to Ireland and the west of Scotland. The eastern part of the county also abounds in coal, particularly Tindale fell, Talkin, and Blenkinsop, which produce the chief supply for Carlisle, Brampton, Penrith, and the intermediate country. Some of this coal is now exported at Port Carlisle to Ireland and Scotland. There are collieries at Gilcrux, Arkleby, Oughterside, Bolton, and Hewer-hill. Limestone is very abundant in many parts of the county. In some places it is burnt in great quantities for exportation, particularly to the west of Scotland. At Catlands the limestone is overlaid by the coal measures on all sides. Plumbago, or black lead, is found, in irregular masses, in a rock of gray felspar porphyry at Borrowdale near Keswick. A little cobalt has been got at Newlands; and antimony near Bassenthwaite; but this is not, we believe, now worked. Lapis calaminaris, small quantities of manganese, galena, iron pyrites, and spar of various kinds and of different colours and forms are found in several places. Slate of a pale blue colour and of the finest quality is plentiful in Cumberland.

The agriculture of the county has improved considerably of late years, and great quantities of corn and produce of various kinds are now exported. The chief exports are from Port Carlisle, Whitehaven, Workington, and Maryport, and consist of cattle, sheep, poultry, grain, potatoes, butter, bacon, &c. The land being divided into small farms, the dairies are necessarily on a small scale, though their produce is excellent, and bears a high price in the market.

The cotton and woollen manufactures are

carried on to a small extent in Cumberland, and there are manufactures connected with the mining products; but it can scarcely be called a manufacturing county.

CUMIN, or CUMMIN, is the fruit (miscalled the seed) of a plant cultivated in the East. Externally it is of a grayish yellow colour, and is larger than that of caraway or anise. The odour is strongly aromatic and rather unpleasant; the taste is warm, bitter, and disagreeable. The odour and taste are mainly due to a volatile oil which is more abundant in this fruit than in most umbelliferous plants: one pound yields half an ounce of this oil, according to some authorities; while ten pounds yield only three ounces and a half, according to others. Notwithstanding this large quantity of oil, the fruits are frequently eaten by insects.

The disagreeable odour of Cumin seems to have gradually discarded it from medicine for man, and restricted its use to veterinary medicine. Its employment in this way may be a relic of its ancient repute, for the Israelites esteemed it highly as a remedy for cattle after the bites of insects. Still it is a valuable drug; it enters into the composition of many curry-powders, but should be introduced into these in very small quantity.

CUMNOCK, in Ayrshire, affords an illustration of the effect even of a trifling manufacture to give a sort of celebrity to a town. Weaving and hand-sewing employ a portion of the population; threshing mills are made here, and pottery was formerly extensively made; but the manufacture which has rendered the village somewhat celebrated is that of the well known wooden snuff-boxes, which are so generally admired.

CURRANT, a well known hardy fruit, produced by two species of the genus *Ribes*. The red currant is remarkable for the mixture of sweet and acid in its fruit, and for the beauty of its semitransparent red or yellow berries. In the fruit of the black currant, a powerful and agreeable aromatic principle takes the place of acidity. The currants of the grocers' shops are the dried berries of a small kind of grape, chiefly cultivated in the Morea and the Ionian Islands, Corfu, Zante, &c. Of these dried currants no less than 429,729 cwts. were imported in 1850. A machine has been lately registered by Mr. Weatherley for cleaning dried currants. In the ordinary method, the currants are cleaned by rubbing them in a sieve or cloth. But in Mr. Weatherley's machine, there is a hollow case made of wire gauze; within this is a cylinder or axle, from which radiate bundles of split whalebone. When the currants are put into the case, and the cylinder made to rotate, the whalebone brushes clean them from dirt, and the dirt falls through the meshes of the wire gauze.

CUSCO-CHINA. This bark comes from Cuzco in Peru; but the tree which yields it is altogether unknown. The alkaloid is procured by the same process as is used for cinchonia, which it resembles in its physical qualities, but differs from in its chemical properties. The taste is more bitter, rather heating, and subastringent. It is equally insoluble in water, but easily so in alcohol and in sulphuric æther. It forms with acids salts which resemble those of cinchonia, but have a more bitter taste.

CUSTOMS-DUTIES consist for the most part of taxes levied upon goods and produce brought for consumption from foreign countries; but such duties are also sometimes collected upon exports made to foreign countries, and upon goods and produce passing from one port to another of the same country. Since the abolition of the export duty on coal in 1845, the only duties outwards consist of an *ad valorem* duty of one-half per cent. on the shipment of some articles of British production.

Shortly before Sir Robert Peel's fiscal reforms, there were customs' duties levied on considerably more than a thousand different articles; he reduced this number to 813 in 1842, and to 382 in 1845; and further reductions have still taken place.

The net amount of duties collected in the United Kingdom on imported articles, after the deduction of drawbacks, repayments, &c., in the several years from 1830 to 1850 was as follows:—

1830	£21,622,683
1831	21,272,263
1832	21,714,524
1833	20,892,902
1834	21,282,080
1835	21,873,814
1836	22,758,369
1837	21,849,109
1838	22,121,038
1839	22,958,254
1840	23,153,958
1841	23,302,152
1842	22,356,324
1843	22,450,074
1844	23,864,494
1845	20,196,856
1846	22,168,735
1847	21,539,775
1848	22,477,609
1849	22,194,600
1850	21,904,566

CUTCH, a principality in the west of India, is one of those in which cotton is grown. The cultivation is carried on extensively, and the produce exported in return for grain, of which a sufficiency is not grown for consumption, and which is procured from Gujerat and Sinde. Iron ore occurs generally throughout the country, and in most parts coal is found in abundance. The wool of the Cutch sheep is of long staple but coarse, answering well for the manufacture of blankets and carpeting: the weight of the fleece averages from four and a half to five pounds. Coarse woollen cloths are made and used by the inhabitants.

Mandavee, the principal sea-port of Cutch, is situated on the shore of the Indian Ocean, and is the most populous place in the principality. The port is an open roadstead with a creek; there are 250 vessels belonging to the place, by means of which a very considerable trade is carried on with Zanguebar and the whole east coast of Africa, with the Red Sea and Arabia, with the Persian Gulf, Mekran and Sinde, and with India as far as Ceylon. The vessels employed in this traffic vary from 25 to 200 tons burden; they carry a large lateen sail, and have two masts, but are never decked; they are navigated by native pilots, who have acquired the use of the quadrant, and steer by charts. The most valuable branch of the trade of Mandavee is that carried on with the eastern coast of Africa, a distance of 3000 miles, whence the merchants of Cutch procure ivory, rhinoceros hides, and other valuable articles. The principal article of export is cotton.

CUTLERY. Nearly all the cutlery used in this country, and a vast quantity of that which is met with in other parts of the world, is made at Sheffield. It is one of those curious examples which the history of manufactures often presents, of the settlement of a particular branch of industry in one spot, where the skill of the inhabitants becomes habituated to that particular manufacture.

Cutlery is generally considered to comprise most steel cutting instruments, such as table knives, pen and pocket knives, lancets, razors, scythes, saws, scissors, shears, spades, edge tools, &c. Swords would also come under this classification; but it is remarkable that swords are made principally at Birmingham, and not at Sheffield. The number of processes to make each kind of cutting instrument depends on various circumstances. In making a *table-knife*, for example, a piece of bar steel is cut off; it is forged to a rough blade shape; a small piece of iron is welded to it, and forged to form the tang; the shoulder, between the tang and the blade, is fashioned into shape by swaging or hammering it with a die; and the knife thus far finished, is tempered, ground, sharpened, and polished.

In making a *fork*, the end of a steel bar is first made red hot; it is hammered so as to give a rough approximation to the shape of the shank or tang; it is again heated, and a blow from a die or stamp gives the proper contour; the prongs are cut out by a powerful blow from a stamp of peculiar form; and the fork is finally annealed, hardened, ground, and polished. It is this process of fork-grinding which has so often been made a subject for comment; the fork is ground *dry* upon a stone wheel, and the particles of steel and grit are constantly entering the lungs of the workmen, thereby ruining the health and shortening the duration of life. Many contrivances have been devised for obviating this evil; but the fork-grinders have not seconded these efforts so zealously as might have been anticipated.

In making *pen* and *pocket* knives, a slender rod of steel is heated at the end, hammered to the form of a blade, and carried through many subsequent processes. But the putting together of these hinged knives requires more time than the making of the blades, and affords a curious example of minute detail. When the pieces of ivory, pearl, tortoiseshell, horn, bone, or other substance, which are to form the outer surface of the handle, are roughly cut to shape; when the blade has been forged and ground; and when the steel for the spring is procured—the whole are placed in the hands of a workman, who proceeds to build up a clasp knife from the little fragments placed at his disposal. So many are the details to be attended to, that a common two-bladed knife has to pass through his hands seventy or eighty times before it is finished.

In making a *razor*, more care is required than in most kinds of knife making. A piece of steel is heated and hammered at the end; it is again hammered on a round anvil to make the blade concave; by cutting and forging it is brought to the peculiar shape which a razor-blade often presents; it is ground upon a small grindstone, to give the concavity without which it could not be sharpened to the requisite degree; it is tempered with very great care, and is finally polished. The recently-patented *Guard* razors are somewhat complicated contrivances for shielding the skin of a clumsy user from being cut.

The making of *handles* for cutlery is a very large department of Sheffield industry. Mother o' pearl, ivory, ebony, bone, horn, &c., are purchased in large quantities; and the making of each kind of handle or haft constitutes a distinct employment.

A method was introduced a few years ago of ornamenting cutlery by transferring the impression of an engraving to the surface of the steel. The engraving may be from a copper plate or from a wood cut, printed in the one case by the roller-press and in the other by the printing-press. The ink is a composition of asphaltum and bees-wax. The impressions on paper are applied to the steel, and an acid liquor fixes the device.

Solingen, in Germany, is designated the Sheffield of that country; and it is expected that at the forthcoming Exhibition a trial of skill will be made in this as in other departments of manufacture.

CYANOGEN, or bicarburet of nitrogen, is a gaseous compound, discovered by Gay Lussac in 1815. It is colourless, and has a peculiar and pungent odour. It is inflammable, and burns with a purple flame; but a taper immersed in it is extinguished. It is not readily decomposed by heat. It is an essential ingredient of *Prussian Blue*. Combined with oxygen it forms *Cyanic Acid*, a sour liquid.

CYANOMETER, is an instrument which was invented by M. de Saussure for the purpose of enabling an observer to ascertain the intensity of colour in the sky. It consists of a circular plate or ring, of metal or pasteboard, on the surface of which, about the circumference, is a band divided by radii into fifty-three equal compartments. One of these is white, and those which follow in succession are coloured with blue of different degrees of intensity from the most faint to the deepest which can be produced; the rest of the compartments are coloured with mixtures of Prussian Blue and Ivory Black, and gradually increase in darkness to the last division, which is quite black. The colours laid on are such, that at equal distances from the eye the tint in each compartment cannot be distinguished from that of the next inferior to it, when the latter is near the eye. The white space being zero, the others are marked, in succession from thence, with the numbers 1, 2, 3, &c.

In using the instrument, the observer, who should be in the open air, holds it up between himself and that part of the sky at which he intends to ascertain the colour, when the compartment which, to the eye, appears to be exactly equal to it in tint expresses by its number the required intensity of the blue colour in that part of the sky. Such an instrument is useful in meteorological observations.

CYCLOGRAPH, or ARCOGRAPH, is an instrument for drawing arcs of circles without centres, used in architectural and engineering drawing when the centres are too distant to be conveniently accessible. Bricklayers and masons when they wish to strike an arc upon the face of a wall, have recourse to a very simple but perfect mode of accomplishing the object, by driving a nail into the wall at each extremity of the intended arc, and then nailing two straight laths or rods together at such an angle, that while their external sides or edges are in contact with the nails driven in the wall, their apex or meeting point shall touch the crown of the required arc or arch. When secured to each other at the required angle, the laths are so moved that, while they remain in contact with the nails, the apex may traverse the whole distance from one nail to another, in doing which it will describe the required curve, which may be marked on the wall by a piece of chalk carried round with it. The same plan may be adopted in drawing on paper, substituting pins for the nails, and a piece of stout cardboard, cut to the required angle, for the laths. Mr. Rotch's *Arcograph*, Mr. Alderson's *Curvilinead*, Mr. Warcup's *Curvograph*, and Mr. Peter Nicholson's *Centrolinead*, all described in the 'Transactions' of the Society of Arts, are instruments for producing somewhat similar results. The centrolinead may be compared to a T-rule, in which the transom consists of two pieces adjustible to any required angle with each other, and the centre of which, answering to the apex of the cyclographs above described, is precisely on a line with the fiducial or drawing edge of the stem or long limb of the rule. The instrument being once adjusted to the required angles, and having its angular transom laid against two fixed pins, just like the angle of a cyclograph, any number of converging lines may be drawn by it as readily as parallel lines are drawn by a common T-rule.

CYLINDER. The manufacture of cylinders for steam engines and other purposes is noticed under BORING and FOUNDING.

CYLINDRICAL LENSES are made by grinding each of the opposite surfaces of a plate of glass in the form of the segment obtained on cutting a cylinder by a plane parallel to its axis. Two segments thus obtained being placed with their plane surfaces in contact, and so disposed that straight lines parallel to the axis of the cylinder drawn on the convex surface of one may be at right angles to lines similarly drawn on the other, would constitute a lens of the kind here indicated.

Lenses of this kind were devised and executed soon after the commencement of the present century by an optician of Paris, who introduced them as eye-glasses in spectacles in place of the usual spherical lenses. This person afterwards, conceiving that in such lenses the chromatic aberration was destroyed, attempted to employ them as simple object-glasses for telescopes; but they have since been found unfitted for this purpose.

CYMAMETER. Mr. Fenn registered under this title, in 1850, an ingenious contrivance for making copies of the outlines of capitals, cornices, mouldings, and other architectural figures. It consists, essentially, of a large number of very thin laths or plates, all of equal length and placed one on another; when one end of these laths is pressed against a moulding or other device, the other end is driven out, the laths which press against a convex surface being driven out further than those pressing against a concave surface; so that the outer extremities of all the laths form collectively a type of the moulding or device.

This is simply a new application of a principle practised long ago for other purposes.

CYMBALS. These musical instruments are traceable to the remotest ages of antiquity, and, with no great change in form, are still used by the moderns. They are always in pairs, are made of brass, and are nearly flat, about twelve inches in diameter, the central part sunk in; and at the back of the sunken poition is a strap by which each instrument is held.

CYPRUS. This fine island, which has remained in the hands of the Turks for nearly three centuries, is naturally fertile. Cotton of the finest quality, excellent wine, and all kinds of fruit are produced; but agriculture is in a most backward state. Besides the productions already named, madder, opium, oranges, lemons, pomegranates, &c., are grown. The carob-tree abounds in some districts; its succulent pods are exported to Egypt and Syria, while the fruit called St. John's Bread is used as an article of food. On the mountains are forests of fine timber. Sheep and cattle thrive. Copper, asbestos, talc, rock-crystal, and various other minerals are found. Salt is made on the sea-shore. Game and fish are plentiful. But these natural advantages are made of little account; for under the Turkish rule the inhabitants are oppressed and miserable, and show little industry, either productive or commercial.

D

DACCA, in Bengal, is principally known in Europe for its manufactures of cotton goods. The striped and figured muslins of Dacca were long celebrated throughout the world. The beauty and delicacy of these fabrics were once unrivalled; but of late years the weavers of Paisley and Manchester have so successfully competed with those of Dacca, that a large proportion of the families in that district, who have for many generations employed themselves in their production, have been compelled to adopt other pursuits. Another reason for this change may be found in the altered condition of the former lords of the country, among whom the curious fabrics of Dacca were held in the highest estimation, and who are now unable to gratify their taste for costly apparel.

DADO, a term for the die or plane face of a pedestal. The dado employed in the interiors of buildings is a continuous pedestal, with a plinth and base-moulding, and a cornice or dado moulding surmounting the die. This continuous pedestal, with its moulding, is constructed of wood, and is usually about the height of a chair-back, and is now used to protect the stucco-work or paper of the wall. Some dados are panelled.

DAIRY; DAIRY FARMS. A dairy-house should be situated on a dry spot somewhat elevated, on the side of a gentle declivity, and on a porous soil. It should be on the west or north-west side of a hill if possible, or at least sheltered from the north, east, and south, by high trees. Coolness in summer, and an equable temperature in winter, are essential requisites in a dairy.

The following description of a Netherland cow-house and dairy under one roof combines all that is useful, with considerable neatness internally and externally:—It is a building about sixty feet long by thirty wide, with a verandah running round three sides of it. The dairy-room is sunk below the level of the soil, and is paved with brick. The sides are covered with Dutch-tiles, and the arched roof with hard cement. The cow-house, like all in Holland, has a broad passage in the middle, and the cows stand with their heads towards this passage, which is paved with clinkers, or bricks set on edge. Their tails are towards the wall, along which runs a broad gutter sunk six or eight inches below the level of the place on which the cows stand. The cows stand or lie on a sloping brick floor, and have but a small quantity of litter allowed them, which is removed every day and carried to the dung-heap or to the pig-sties. Whenever the litter is removed, the bricks are swept clean; and in summer they are washed with water. In Holland the cows' tails are kept up by a cord tied to the end of them, which passes over a pulley with a weight at the other end, as we see practised with horses that have been nicked; thus they cannot hit themselves, or the person who milks them. The cows are fastened in a way so as to give them freedom of movement without striking their neighbours with their horns. The mangers or troughs are of wood, or of bricks cemented together, and are kept as clean as all the rest of the cow-house. In Switzerland the cow-houses are similar, but there is also a rack, the back of which towards the passage shuts up with a board on hinges.

The utensils of the dairy, such as pails, churns, vats, &c., are usually made of white wood, and are easily kept clean by scalding and scouring. Leaden troughs are used in large dairies. Brass pans have the advantage of being readily warmed on a chafing-dish in winter. In Devonshire tin or brass pans are frequently used instead of earthenware. In Holland the milk is invariably carried in brass vessels. Cast-iron pans have been invented, which are tinned inside. Glass and white ware are used for the same purpose; especially owing to the repeal of the glass duties, since which time glass has become extensively used in dairies.

The dairy farms of England are chiefly in Gloucestershire, Devonshire, and Cheshire. They require a smaller capital than arable farms of the same extent. The chief outlay is in the purchase of cows.

The principal duties of the dairy are noticed under BUTTER; CHEESE; CHURN; MILK.

DALAGO'A or DELAGOA BAY, on the eastern coast of Southern Africa, is much frequented by whalers, as the bay abounds in whales. The Portuguese have a small fort on the western shore of the bay. Supplies are abundant and cheap; piece-goods, buttons, beads, cutlery, brass wire, old clothes, iron, copper pipes, spirits, sugar, &c., are readily taken for bullocks, fowls, vegetables, fish, hippopotami teeth, gold dust, ambergris, &c.

DALMATIA. As a part of the Austrian dominions, the produce and industry of Dalmatia have been briefly noticed under AUSTRIA.

DAMASCENE WORK. The damask, damascene, or damascus work, so often met with in choice specimens of metal manufacture, especially on the old Damascus sword-blades, is a method of producing a pattern or design by encrusting one metal with another. It was introduced into Europe from the Levant, where it was much practised in the middle ages, especially at Damascus. The metals usually employed were silver or gold on iron or copper, gold on silver, or silver on gold; but any other combination would equally come within the principle of the art.

There were several different modes of damascening. If the metal to be damascened were hard, its surface was wrought into fine lines crossing each other, and the designs were afterwards traced upon it; the design marks were filled in with the metal inlay, which was fixed by a strong pressure or by hammering; and the entire work was then burnished, by which the lines uncovered by the incrustation were erased, and a fine polish given to the surface. Another method was that of hatching the incised lines only, and of fixing the incrustation as before. In a third method, when the incrusting metal was of a ductile nature, the pattern was simply incised in outline, and the body of the design left on the same level as the rest of the surface; a thin sheet of metal was then laid upon these designs, and fixed by the insertion of its edges into the exterior incisions; the incrustation was thus in relief, and was afterwards occasionally engraved. A fourth kind of damascene work partook of the nature of *picqué*, or a design formed by small pins or studs, much in vogue in England in the seventeenth century.

Various European cities had artists who practised damascening; but Venice and Milan were the chief.

At the Mediæval Exhibition of 1850, several beautiful specimens of damascene-work were collected, including candlesticks, tankards, inkstands, shields, etuis, swords, &c.; but the most exquisite was Cellini's far-famed shield, presented by Francis I. to Henry VIII., and now the property of Her Majesty. It is made of embossed steel, damascened with gold and silver. It has represented upon it in compartments, scenes from the history of Julius Cæsar, each consisting of numerous figures in relief of the most highly finished execution.

DAMASCUS is the chief emporium of the trade in European manufactures with Bagdad, Bassora, Persia, and the neighbouring countries, whither goods are conveyed by camels; it is also a place of great manufacturing industry, and contains silk factories, cotton printing and dyeing establishments, tobacco factories, copper and iron foundries, glass-works, soaperies, &c. There are nearly 800 merchants engaged in the sale of damask cloths alone. The manufacture of Damascus blades, once so famous, no longer exists. Saddles and bridles, both rich and highly finished, fine cabinet-work, and rich jewellery are among the articles of Damascus industry.

DAMASK, a peculiar kind of woven cloths composed both of flax and of silk, which are believed to have been originally brought from Damascus. Silk damask weaving was introduced into England from Flanders in the latter half of the 16th century, and linen damask weaving in the latter half of the 18th. Damask cloths are of thick texture, but fine in quality, and the weaving of them puts into requisition all the skill of the weaver for the production of the elaborate patterns which they bear.

DAMSON, or DAMASCENE, is the well-known name of a kind of plums, cultivated in this country for the sake of their hardiness and prolific habits. They are a mere form of the domestic plum, from which there are no certain characters to distinguish them, except the abundance of their late oval fruit, and the property they possess of propagating by suckers. All the varieties are used for kitchen purposes principally, and are generally confined to the gardens of cottages or farm-houses where the quantity of produce is more valued than its quality. Much the finest variety of this sort of plum is that called the Shropshire Damson, which is extensively multiplied in the nurseries by grafting.

DANUBE, called by the Germans the *Donau*, and by the Hungarians the *Duna*, is a river of the first rank, and the second of European rivers, being inferior only to the Volga. Its course is calculated to be about 1770 miles, and the surface drained by it and its numerous tributaries probably exceeds 300,000 square miles. Steam navigation is established on the Danube. The voyage is divided into several *strecke* or portions — Donauwörth to Ratisbon, Ratisbon to Linz, Linz to Vienna, Vienna to Pesth, Pesth to Orsova. From Orsova, or rather from a station below it called Drenkova, to Skela Gladova, a distance of 54 miles, the river is not navigable except for light cutters, owing to the rapids, whirlpools, and dangerous ledges that occur in this interval. Passengers are conveyed between these stations in carriages along a splendid road cut in the rocks that line the river. The remaining portions of the voyage are from Gladova to Galatz, Galatz to Odessa, Odessa to Constantinople. In consequence of the melting of the snows the Danube rises from June to the middle of July, and does not begin to sink till the middle of August. This period is very favourable to the navigation of the river from the increased depth of water.

DANZIG. This important Prussian city owes its commerce and prosperity to its harbour, and to the extensive inland navigation afforded by the Vistula and its numerous tributaries, by which the corn, timber, and other products of Poland and the Ukraine are conveyed to Danzig. The town is traversed by the Radaune and Motlau, feeders of the Vistula.

There are yards and slips for ship-building; sugar refineries, spirit and liqueur distilleries, breweries, and copperworks; and manufactories of silks, woollens, linens, leathers, hats, and gloves, soap and starch, earthenware, arms, steel-ware, hats, tobacco, &c. The town has a very considerable export trade, consisting of corn, timber, flour, linseed, rapeseed, deals, staves, ashes, quills, spirits, black beer, spelter, wool, flax, hemp, &c. The imports are composed of wine, brandy, rum, raw cotton, coffee, herrings, iron and steel wares, indigo, lime and plaster, sugar, salt, tobacco, &c. The gross value of the imports is about 400,000*l.* annually; about one-fourth of the imports in value are brought from England. The gross value of the exports nearly reaches two millions sterling annually, of which England takes nearly three-fourths.

DARIEN. The projects for making a railroad or a canal over this isthmus will be better noticed under PANAMA.

DARLINGTON. The trade of Darlington is considerable: for a long period the principal manufactures were of camlets and other woollens; sixty years ago moreens and similar stuffs were made: the woollen manufacture was superseded in a great degree by that of linens, as huckabacks, diapers, sheetings, and checks; but this branch of industry has also declined, and the chief occupation of the inhabitants now is combing wool and making woollen yarn (which is used for imitation India shawls, Brussels carpets, &c.), spinning flax, grinding optical glasses, and the manufacture of brass and iron. There are very extensive worsted mills.

DARTFORD. The first paper-mill erected in this country is usually stated to have been at Dartford on the site of the powder-mills; but this has lately been disproved in 'Notes and Queries.' The first mill established in England for rolling and slitting iron is also said to have been near Dartford. The trade of Dartford is considerable. There are chalk-pits near the town; oil, powder, and paper mills in the neighbourhood on the river Darent; two corn-mills on a large scale worked by water-power and steam; also a large iron foundry and manufactory of machinery. At a short distance from the town are a cotton-mill and silk printing works.

DAVY, SIR HUMPHRY, must be regarded as one whose discoveries have afforded important aid to manufacturing industry, although relating in the first instance to scientific chemistry. He was born at Penzance in 1778. His father was a carver in wood. In the year 1795 he was apprenticed to Mr. Borlase, a surgeon and apothecary of Penzance, where he appears to have laid down an extensive plan of study, not merely of the sciences which related to his profession, but the learned languages, mathematics, history, &c. In 1798 he was considered competent by Dr. Beddoes to take charge of an establishment which he had founded at Bristol under the name of the Pneumatic Institution. In the next two years he wrote several essays on chemical subjects; and in 1801 he came to London, and on the 25th of April he gave his first lecture at the Royal Institution. He began with the history of galvanism, detailed the successive discoveries, and described the different methods of accumulating it; and on the 31st of May, 1802, he was appointed professor. From the year 1800 to 1807 a great variety of subjects attracted his attention, especially galvanism and electro chemical science; the examination of astringent vegetable matter in connection with the art of tanning; and the analysis of rocks and minerals with relation to geology and to agricultural chemistry. In November 1807, his second Bakerian Lecture was read, in which he announced the most important and unexpected discovery of the decomposition of the fixed alkalies by galvanism, and of the metallic nature of their bases, to which he gave the names of potassium and sodium. From the year 1808 to 1814, twelve papers by Davy were read before the Royal Society, and published in their 'Transactions,' relating to various chemical and electro-chemical subjects, and all containing details of original and important researches. He showed that the earths barytes, strontian, lime, and magnesia, are oxides of metals, and he laid the foundation which has enabled other chemists to prove the same thing in respect to other earths. He made important additions to the existing knowledge concerning sulphur, phosphorus, carbon, chlorine, and alkalies, and indeed extended almost every department of chemical science. In 1810 he published the first volume of his 'Elements of Chemical Philosophy,' which, although it bears marks of haste, contains much interesting matter: no further portion of this work was printed. His elements of Agricultural Chemistry,' which appeared soon after, is a work containing much useful matter, and replete with sound and practical views of the subject. One of his greatest inventions was that of the miner's safety-lamp, the first paper in relation to which appeared in the 'Philosophical Transactions' for 1815, and the last in 1817.

All Davy's discoveries have since been turned to account in industrial processes, especially in manufacturing chemistry. This great chemist died in 1829.

DEALS are boards of fir above 7 inches in width, and of various lengths exceeding 6 feet. If less than 7 inches wide, they are called battens. The duty on deals or boards since April 5, 1848, is 1*l.* the load, if imported from a foreign country; but if from a British possession it is 2*s.* the load.

DECOCTIONS are formed by subjecting the harder parts of plants, which are not easily penetrated by liquids, or are insoluble in water of a low temperature, to the process of boiling, generally in water, but sometimes in oil. By this means much of the substance is dissolved, and the active principles of the plant are imbibed by the fluid, which is then used medicinally, either internally or externally. This method of extracting the medicinal properties of plants is inadmissible when their powers depend upon any aromatic or volatile principle, such as essential oils, which are dissipated by the high temperature. In many other instances this process is not only unnecessary, but injurious, being employed when infusion is sufficient, even when cold water is used for the purpose of infusion. The heat is apt to destroy the very principles which are desired to be obtained in many cases; and this process is most suitable to those substances which are both nutritious and medicinal, such as Iceland Moss. Many principles which are dissolved by the water at a boiling temperature are deposited by it on cooling; on which account the liquid should always be strained while hot, and the contents of the bottle shaken up before each dose be poured out. Aromatic liquids are frequently added to the fluid after it is strained; or the aromatic substance may be placed at the bottom of the vessel into which the hot decoction is strained, and, after being allowing to infuse for a few hours, may then be applied to the use intended. A better method however is to add some aromatic tincture after the straining, as the spirit retards the tendency to decomposition, while it imparts the flavour and qualities of the substances from which it had been prepared.

The decoctions employed in medicine are so numerous, that a mere list of them would occupy considerable space. They are prepared from bark, berries, rind, root, stems, seeds, pods, kernels, &c.

DEER SKINS, are tanned into leather for various purposes. From 40,000 to 80,000 are imported annually.

DELFT, a large town in the province of South Holland, was formerly famous for its pottery, to which it gave its name; but this manufacture has been supplanted even in Holland by the superior pottery of England; the earthenware of Delft is now of the coarser kind, and not more than 200 persons are employed in the manufacture. Manufactures of woollen cloths and tobacco-pipes are carried on. The blue Delft ware, and carpeting from the same town, will find a place in the Industrial Exhibition of 1851.

DELHI. This once-celebrated Indian city retains something of its former manufacturing and trading eminence. The commerce is still extensive, particularly in shawls, of which it is a great mart. They are brought from Cashmere in large quantities, some plain, to have borders sewn upon them, and to be embroidered in gold and silk. The goldsmiths are much celebrated for the elegance and delicacy of the jewellery which they produce.

The following announcement in the public journals is interesting, in connection with the forthcoming Exhibition of Industry. "The renowned Delhi seal-cutters have nearly finished the seals which are being cut for the Queen and Prince Albert, under the superintendence of Budi-oo-deen Ulee Khan. The seal for the Queen is described as a cornelian, with the corners cut off, on which is engraved an inscription in Hindostanee. Prince Albert's seal is cut on a blood-stone. The inscriptions are in the true grandiose style of the East. Besides these, Budi-oo-deen has prepared two beautiful emeralds for seal rings, to be presented by himself as specimens of his skill; one for the Queen, three eighths of an inch in length, by two-eighths in breadth."

DEMULCENTS are medicinal agents which have the property of protecting sensible surfaces from the action of irritating matter, by hindering it from coming in direct contact with them. When much water is present in any demulcent liquid, the action is partly that of a diluent, but the chief benefit results from the bland nature of the substance, or from its viscidity. Demulcents are either solutions, such as mucilage of gum arabic, or certain substances mechanically diffused through water or milk, such as wax, spermaceti, or suet.

DEMURRAGE, in shipping affairs, is the term used to denote the money payable to the owner of a ship on the part of the shippers or consignees of goods, as compensation for detention beyond the time stipulated for her loading or discharge, as the same is expressed in the charter-party or bills of lading.

DENMARK is principally an agricultural country. The most fertile parts are the islands of Laaland and Falster, and next to them Seeland and Funen; but agriculture is most skilfully carried on in the Baltic districts of Holstein. The Danes however are not generally good agriculturalists. Of the whole area, about two-thirds are appropriated to arable land; one-twelfth to pasture and meadow; and one-twentieth to woods and forests. The average yearly produce is stated at about 8,000,000 quarters of corn; 2,000,000 tons of potatoes; and a proportionate quantity of other produce. Peas and pears, rapeseed, flax, hemp, and tobacco are grown: fruits and table vegetables are comparatively small in produce. The fine forests once possessed by Denmark have been allowed so to decay, that the inhabitants are obliged to import wood from other countries. The chief timber-trees are pine, beech, oak, and birch.

Denmark possesses no mines or metals whatever; nor any minerals of importance, except coals, freestone, and salt. Amber is collected on the Hitze, a sandbank on the western coast of Jutland. Potters' and porcelain earths are also obtained. Peat is got wherever there are swamps, and every village in those parts has bog lands assigned for its supply.

Manufactures are but slightly developed in Denmark. Altona produces silk, woollen, and cotton goods, leather, soap, refined sugar, and tobacco. Lace is made on a very extensive scale in and about Tondern. There are large tobacco manufactures, but they are said not to produce more than one-eighth of the quantity consumed. The woollen and cotton manufactures are small in amount. There are a few establishments for linen, gloves, paper, and ironware. Straw hats, sail-cloth, glass, soap, leather, saltpetre, gunpowder, and arms, plated goods, china, and earthenware, beer and spirits, thread, refined sugar, soda, and potashes are among the productions of Danish industry. The brandy distilleries are rather numerous. The peasants' families make their own woollen clothing in general, which is composed of a coarse stuff termed wadmel; and indeed there are few articles of domestic use, whether utensils or for apparel, which are not made by their own hands.

There is probably no country in Europe better adapted or more favourably situated in many respects for commerce than Denmark. It is the key of the Baltic, and possesses peculiar advantages for a ready and cheap intercourse with all the maritime nations of Europe. Copenhagen, the capital, is the central point of the Danish foreign trade, which has been greatly favoured by the neutral policy which the government has endeavoured to pursue during the last hundred years and more. Navigation, in which about 50,000 hands are employed, is a great source of profit to the country, for the Danes navigate their vessels on cheaper terms than many of their competitors, and are excellent mariners, on which account they are the carriers for other countries, particularly to the Mediterranean and Levant. There is a brisk intercourse by sea between the several ports. The chief places of trade are Copenhagen, Altona, Kiel, Koersoer, Helsingor, Odensee, Viborg, Randers, Flensberg, Schleswig, Aalborg, Rendsburg, Tondern, Aarhus, Gluckstadt, Neustedt, and Itzehoe. Railways have been recently formed from Altona to Gluckstadt, Rendsburg, and Kiel.

Denmark exports grain, butter, cheese, brandy, salted and smoked meats, horned cattle, horses, skins and hides, oil, eider-down, fish, tallow, bristles, &c., and imports wines, salt, silk, wool, cotton, timber, coals, colonial produce, brandy, spirits, glass, drugs, &c.

The British produce and manufactures exported to Denmark in 1846-7-8 were of the following values:—

1846	..	..	£340,318
1847	..	..	253,701
1848	..	..	296,466

Of the articles thus exported, cotton, coals, and iron manufacture comprises the largest items.

The imports from Denmark into Great Britain in 1848, comprised, among other items, butter 8,056 cwts, corn about 1,000,000 qrs., flax 9,000 cwts., flax and other seeds, 45,000 qrs., seal skins, 14,000, wool 1,500,000 cwts.

The Danish vessels which left British ports in 1849 amounted to 1708, and those which entered were 1885. These vessels are small, however, the average tonnage being under 80 tons.

DENSITY, properly speaking, has no absolute meaning, but it is a term which may be considered as representing the number of material particles in a body. Thus gold is more dense than air, because probably, under equal volumes, gold contains a greater number of particles than air. The measure of the density of any body is called its specific gravity. [SPECIFIC GRAVITY.]

DERBY. The principal manufactures of this interesting town are of silk and cotton goods, porcelain, jewellery, and ornamental articles made of the various kinds of spar found in the county, red and white lead, lead pipe, sheet lead, cast iron, ribbed stockings, and bobbin-net, and other lace. Silk hosiery is extensively made. There is a considerable printing and publishing establishment, besides several printing offices.

In the early part of the 18th century the art of spinning or 'throwing' silk, which had been exclusively possessed by the Italians, was introduced into Derby by a Mr. Crotchet, who did not succeed in business. In 1717 Mr. John Lombe, who had obtained access to the machinery of the silk throwsters of Piedmont in Italy, agreed with the corporation of Derby to rent an island or swamp in the river Derwent, 500 feet long and 52 feet wide. Here he erected, at a cost of 30,000*l*., an immense silk-mill, now the property of the corporation, the lease having expired. In 1718 Lombe took out a patent, and was proceeding successfully in his business when he died. He was succeeded in his mill by his brother William, and afterwards by his cousin, Sir Thomas Lombe. The accounts of the machinery of this immense mill have been much exaggerated: the wheels have been said to amount to 26,000; Hutton, who served an apprenticeship of seven years in the mill, states that the number of wheels was 13,384. The whole machinery was moved by one water wheel. Many throwing mills have since been erected at Derby, and this branch of industry may be regarded as the staple of the town. The cotton manufacture is of later introduction and of smaller extent. The spars of the county, especially the fluor spar, or 'blue John,' are wrought into vases and other ornaments, and the black marble of Ashford into vases, columns, chimney-pieces, &c.

The Derby Arboretum is an honour to the town, both or its own beauty, and for the circumstances under which it was formed. This Arboretum is a piece of ground of about 16 acres in extent, well laid out and arranged with trees and shrubs, so as to combine instruction with recreation. The original Arboretum, a piece of ground about 11 acres in extent, carefully arranged by the late Mr. London, was given to the town by Joseph Strutt Esq.;

an adjoining portion of about 5 acres has since been purchased and laid out in a similar manner. The inhabitants are admitted to the grounds on payment of an admission fee, the proceeds of which defray the expenses of maintaining the establishment.

DERBYSHIRE. This county is rich in mineral strata. The coal-measures underlie the magnesian limestone, and crop out from beneath it on the west. These coal measures form part of that important coal field which occupies a considerable part of the west riding of Yorkshire, and extends into Nottinghamshire and Derbyshire, being bounded on the east by the magnesian limestone, and on the south by the red marl. The strata range from north to south, and dip to the east. The Derbyshire portion of this coal field is east of a line drawn from between Hathersage and Sheffield to Little Eaton, near Derby. Every variety of coal seems to be found in this field, hard stone coal, cannel, peacock, and caking coal. The coal-pits in Derbyshire are dispersed over the coal field, and are very numerous, especially about Chesterfield and Alfreton, and in the district south and west of the Cromford and Erewash canals. The beds which lie between the seams of coal are worked for various purposes. The workings of the ironstone are generally begun at the surface, and pursued until they become dangerous from the loose nature of the stratum in which they lie. The ironstone which is marked with impressions of mussel shells (called the mussel band) is worked as an ornamental marble. From the gritstone beds are quarried grindstones for cutlers; the binds, where they are hard and black, are used as black chalk; others, when decomposed, make good brick earth; the clunch is sometimes of that kind which is used for fire-bricks; where it crops out to the surface it becomes soft clay. Potter's clay, of various colours and qualities, occurs in this coal-field.

Black marble is quarried for ornamental purposes. One of the beds of limestone contains white chert or china stone, which is extensively used in the Staffordshire potteries. The beautiful fluor spar called 'Blue John,' from which vases and other ornaments are made, is found in a mountain of limestone. Numerous veins of lead, zinc, iron, manganese and copper, also occur.

A large proportion of the land of this county is in permanent pastures, of which some are very rich. Derbyshire cheese is noted as of good quality, and the best is often sold for Cheshire or Gloucester when made of the shape and colour of these cheeses. The common Derbyshire cheese is not generally coloured; it resembles some kinds of Dutch cheeses, and keeps well.

At Cromford, in this county, the late Sir Richard Arkwright erected a spacious cotton-mill on the left bank of the Derwent; it is now occupied by the Messrs. Arkwright, his grandsons, who employ in these mills and those at Masson, a little higher up the Der went, several hundred persons. Lead mines are worked in the neighbourhood; lapis calaminaris is ground and prepared, and red lead manufactured. At Dronfield manufactures are carried on in iron goods, such as railway wheels, cast iron chains and nails, axes, chisels, and other edge tools, and agricultural implements. At Heanor are manufactories for cotton goods, hosiery, and bobbin-net lace. In and near Ashford there are extensive marble works where the black and coloured marbles which are quarried in the neighbourhood are wrought into chimney-pieces, tables, slabs, &c; there are also quarries of lime-stone; and lead mines. Scythes and reaping hooks are largely manufactured at Beighton and at Hackington. At Clay Cross and in its immediate vicinity are extensive collieries and iron works. At Codnor the Butterly Iron Company have extensive iron works and collieries; and iron, lead, limestone, and coal are abundant. At Long Eaton, paper mills and stone quarries give employment to many of the inhabitants. Needles, pins, edgetools and mill stones are manufactured at Hathersage. Ironville is a busy and populous district; the inhabitants are employed in the iron works, smelting, &c.; a national school (in which divine service is performed on Sundays) was erected in 1841, at a cost of 3000*l*., by the Butterly Iron Company, and an infant school has been since erected by the same company; there is also a mechanics institute. At Milford, six miles from Derby, schools have been founded by the Messrs Strutt, who have extensive cotton and bleaching works here, employing 1,000 hands; they have also an iron foundry here, in which all their machinery is cast and made, and gas works at Milford which supply the town of Belper.

Many other towns and villages in Derbyshire carry on some or other of the industrial pursuits noticed in the above sketch.

Derbyshire has some peculiar laws and regulations connected with the working of the lead mines. These laws and regulations are of very high antiquity. The principal part of the county where lead ore is found in any considerable quantity is called 'the King's Field,' and comprehends nearly all the wapentake of Wirksworth and a considerable part of the High Peak hundred. 'The King's Field' has been from time immemorial let on lease. The lessees have each in his respective district a steward and bar-masters. The steward presides as judge in the barmote courts, and with 24 jurymen, chosen every half year, determines all disputes which arise respecting the working of the mines. Debts incurred in working the mines are cognizable in these courts. These courts meet twice a year, or oftener if need be. The court for the High Peak district meets at Monyash, that for the wapentake district at the town of Wirksworth. The office of the barmaster is principally to put miners into the possession of veins that they have discovered, and to collect the proportion of ore to which the lessee of the crown or the lord of the manor has a claim. When a miner has discovered a new vein of ore in 'the King's Field,' he may acquire a title to the exclusive possession of it, provided it be not in a garden, orchard, or high road, by a proper application to the barmaster of the liberty. Should the miner neglect to work the vein, the barmaster may, after a certain time, dispose of it to any one who is willing to try it.

The cottons, the silks, the hosiery, the bobbing net, the iron, the marbles, the pottery, &c. of Derbyshire will all be represented at the Great Exhibition. The quarries in North Derbyshire possessed by the Dukes of Devonshire and Rutland, will be represented in their several products by Messrs. Lomas and Oldfield, the lessees respectively of the marble works of Bakewell and Ashford-in-the-Water; while the splendid amethystine fluor spar, locally designated 'Blue John,' and found exclusively at Castleton in the Peak, will find its way to the Crystal Palace in the elegant form of a colossal Grecian vase, the finest and most important article ever produced from this material. The vase was manufactured at Matlock by Mr. Vallance, who is preparing a number of inlaid black marble tables, vases, candelabra, and other articles peculiar to the county. It is also the intention of Mr. Vallance to exhibit such a collection as will illustrate the peculiar mineralogical and geological character of Derbyshire, as well as the applicability of its products to ornamental purposes.

DESICCATION is the chemical operation of drying bodies. It is sometimes effected by simple drying in the air; sometimes in warm chambers; at others, by paper filters, by the air-pump, by the action of deliquescent salts placed near the body to be dried, and by many other modes.

DESIGN. In the fine arts the word design is employed in two very different significations: in the first place, it is used merely to signify the act of drawing, or representing in lines the form of any object; in the next place it expresses that combination of invention and purpose which enables the artist to compose a picture or a group, without reference to the material in which it is executed. The accurate conception of form and beauty is displayed in the most masterly degree in the ancient Greek sculptures; and in the invention of appropriate attitudes and perfection of physical form the design of the best Greek sculptures cannot be surpassed. But, of all the existing specimens of art, the paintings of the Italian masters display the most consummate excellence in design, especially the Florentine and Roman schools, and among them Raphael's in particular.

In architecture, the design or scheme for a building is shown by means of a series of diagrams or drawings, which, taken one with another, convey a much more exact and complete notion of the whole, both internally and externally, than can be obtained by any other mode of delineation. Such drawings consist of *plan*, *elevation*, and *section*, besides others of *details*, or *parts at large;* and their number will depend, either upon the nature of the building, that is, on its being more or less complex, or as it is intended to show it more or less fully.

DESIGNS, COPYRIGHT AND REGISTRATION. Intermediate in character between the *copyright* of literary productions, and *patents* for mechanical inventions, is the registration of designs in which fine art is more or less exhibited. An act of parliament in 1735 gave a copyright for fourteen years in the arts of designing, engraving, and etching prints: enforcing the right by fine and forfeiture. An act of 1767 extended this right to a period of twenty-eight years, and made it to include the designing of maps, charts, and plans. An act in 1777 increased the power of designers to enforce the observance of the right. Three acts, passed respectively in 1787, 1789, and 1794, gave a copyright for securing the use of new patterns in the printing of linens, cottons, calicoes, and muslins, for a period of three months. An act of 1798 gave a copyright for fourteen years in respect to models, casts, and other sculptures; and another act in 1814 strengthened this right. An act in 1836 extended many of the above copyrights to Ireland. An act in 1838 secured copyright for printing designs in other woven goods, in addition to cottons and linens.

These were the statutes which governed the copyright of designs, down to the time of passing the Registration Act of 1839. This Act declared the existence of copyright in respect to the following productions—patterns to be painted, printed, or worked upon any material; modelling, casting, embossing, chasing, or engraving any new design; a new shape or configuration of a manufactured article. The Board of Trade was empowered to appoint a registrar, deputy registrar, and six clerks, to manage the registration of such designs; and any person so registered had a copyright in his design for three years.

A more comprehensive act was passed in 1842, which gave a copyright for any new and original design, whether applicable to the ornamenting of any article of manufacture, or to the employment of any new material for manufactures. The right was made applicable for the pattern, the shape, or the ornament; and was equally valid whether the pattern were worked by printing, painting, embroidering, weaving, sewing, modelling, casting, embossing, engraving, staining, or dyeing. Arrangements were made for registering the designs, for transferring property in them, and for enforcing penalties in cases of infringement. All designs were classed under one or other of thirteen headings; and the period of copyright was declared to be three years, one year, or nine months, according to the class to which the design belonged.

By another act in 1843 the copyright was extended to designs which, though not actually ornamental, have reference to some purpose of utility in respect to shape or form. All such articles are to be stamped with the word 'registered,' and the copyright in them exists for three years. The registrar is to prepare an index of all such non-ornamental designs; and at the expiration of the copyright, the designs may be copied by any person at the registrar's office, on payment of a fee.

These two acts, in conjunction, guided the proceedings in respect to the copyright of designs for several years; but a statute passed in 1850 has introduced—not so much a change—as an extension of the right. When it was found that the proposal for an Exhibition of the world's Industry was likely to be liberally responded to, it was felt that something ought to be done to secure the copyright of any new designs which might be made public at the Exhibition; and it was mainly to secure this end, that the act was passed which received the royal assent in August 1850. By this act any new design may be *provisionally* registered for twelve months; during this period the proprietor may exhibit his design, and describe it in catalogues, without vitiating his copyright; and at any time during the twelve months he, and he alone, may register the design in the fuller manner set forth in the former acts; but if during this provisional period he should *sell* any of the articles to which this design is applied, he loses the power of completing the registration. Several other clauses are introduced, tending to secure the right of Exhibitors at the Industrial Exhibition of 1851.

The Commissioners have made arrangements for this provisional registration, in respect to new designs to be exhibited in Hyde Park. Until February 1, 1851, the designs were registered at Somerset House, on payment of a small fee; but after that date they are to be registered in the 'Palace of Industry,' free of charge. The Commissioners have issued minute instructions to guide those who are about to register their designs; the designs themselves being placed in two great groups, in respect to *ornamenting* and to *shape*, and each group being divided into classes. The Registrar of Designs has also issued full instructions, explanatory of the operation of the three acts of 1842, 1843, and 1850, and applicable to other purposes besides those of the Great Exhibition.

DESIGN, SCHOOLS OF. In France and in several of the German States, schools in which drawing and the principles of design are taught have been long established. In Prussia there are many elementary schools at Berlin and several provincial towns, in which drawing and modelling from the antique, and geometrical and architectural drawing are taught at an average fee of 12*s*. per year. From these schools the more promising of the pupils are removed to the 'Gewerb Institut' (Manufacturing Institute), and the 'Bau Akademie' (Architectural Academy.) In the former of these two, the studies have reference to all the branches of science or art bearing upon manufactures: in the second, all matters which bear in any way on building, civil engineering, or surveying: in these schools the instruction is gratuitous. The highest class, in which the fine arts are embraced in their widest range, is the Royal Academy at Berlin.

In Bavaria, education in art is mixed up with general education, but it is made to occupy a prominent place. The earliest stages are taught at the elementary schools; the next stage at the gymnasia, of which there is one in each large town; and the last stage at the lycea, of which there are three in the kingdom, at Munich, Nürnberg, and Augsburg; that at Munich being chiefly for architecture and the application of the fine arts to manufactures, that at Nürnberg to metal casting and wood carving, and that at Augsburg to textile manufactures.

In France there are, intermediate between the elementary schools and the royal academies, several others which treat of art in its relation either to manufactures or to science, and which are either supported partly by the state and partly by municipalities, or are private establishments assisted by municipalities; and in most of them a very extensive system of studies is pursued, bearing in various ways on the science and the fine arts of manufactures. The school of art at Lyon, in particular, is an important one in connection with the silk manufacture carried on in that city; and every endeavour is there made to foster taste in manufactures.

The advantages which resulted to the manufactures of the countries in every department requiring the display of taste was so obvious, particularly as displayed in the silk manufactures of France, that a strong desire was felt by the manufacturers and merchants of England to secure similar advantages for this country. Accordingly, in 1836, a school of design was established at Somerset House in connection with the Board of Trade, but under the control of a council and director, with masters in several departments. The school continued to make progress; but the management was not on the whole satisfactory, and early in 1848 the Board of Trade resumed the direct control, and the director and the council were dispensed with. The schools are now under the management of a committee, consisting of the principal officials of the Board of Trade, assisted by three eminent artists in the departments of painting, sculpture, and architecture. The general business arrangements and management of details are assigned to the resident secretary. Admission to students is granted on the recommendation of two respectable persons, for a probationary period of three months, but no instance of rejection has occurred since the alteration in the management of the schools. The terms and hours of attendance have varied more than once since the opening of the school. There are two classes; one in the morning from ten till two, the other in the evening from half past six till nine, on every week day except Saturday. The payment is two shillings per month for morning or evening attendance. Lectures are occasionally delivered by the teachers. There is also a morning school for females, established in 1842, to which the payment is of the same amount. The instruction given is of a character to enable the student to apply the principles of high art to the purposes of the manufacturer and the decorator. The primary classes at the school are three—form, colour, and ornament; and it is said to be purposed to blend colour and ornament into one class. Choice specimens have been obtained from Italy of arabesques, mosaic pavements, terra-cottas, &c. M. Guizot has presented to the school casts from the celebrated gates of the Baptistery at Florence, and there is also a large collection of other casts from the antique, and of Gothic, and other styles of ornament. Specimens of paper hanging, silk, glass, porcelain, bronze, wax ornaments, and other objects have been provided by government for the use of the schools. Books, many of them expensively illustrated, have been purchased, forming a library of reference in matters relating to art and decoration; and some of these books are, under certain regulations, lent out to the students. Books, casts, and other examples of art are supplied by the committee to all the branch schools.

In connection with the School of Design at Somerset House, there are several branch schools. One is established in Spitalfields; and others at Manchester, Birmingham, Coventry, Nottingham, Sheffield, York, Leeds, Huddersfield, Newcastle-on-Tyne, Norwich, Stoke-upon-Trent, Hanley, Glasgow, Paisley, &c.; all of which are well attended, and have been productive of much good. Some of the students have already become teachers in the schools, and many have successfully applied their talents to the improvement of our native manufactures.

There is one other school, that at Edinburgh, which is not in connection with Somerset House. It was established some years previous to that at Somerset House, under the sanction of the Board for the Improvement of Manufactures and the Herring Fishery. It has been well attended, and two of the early conductors at Somerset House were formerly masters there. Its object is nearly the same; the chief distinction is, that in Edinburgh it is the only school of art, while in London there is the Royal Academy for the more aspiring and ambitious.

Under Belfast, Birmingham, Coventry, Nottingham, &c., a few details will be found illustrative of the present state of the Schools of Design in those towns. There are circumstances connected with the Belfast school so interesting that we will quote a portion of the Annual Report for 1850 relating to it, showing how important the mere *wrappers* for woven goods are regarded. After stating that some among the 148 students in 1850 were designers for sewed muslin, and others designers for damasks, the report goes on to say;—'Eleven of the pupils are entered as engravers, and of these several are draughtsmen and designers for the paper bands and envelopes used in tying up the rolls of linen. The value attached to these ornaments in preparing the packets of linen for the foreign markets, the decoration which is lavished upon them, the taste and care with which it is thought necessary to get them up, and the extent to which they are imported into Belfast from London and Paris, render them no unimportant article of trade. In the year 1847, when the establishment of the School of Design at Belfast was first taken into consideration, one stationer at Belfast had made a beginning in the manufacture of these articles, and had a press at work in embossing them. The same stationer has now nine presses at work, and others of the trade have taken up the business. Most of the bands yet made are of an inferior sort, but there are attempts to improve the quality; some are taking the place of the more simple French patterns, and the sale is increasing. The establishment of the school has been happily timed for the encouragement of a branch of trade so favourable to the development of artistic skill, and there is every prospect that by the help of the school the "linen band" will become a home manufacture, and secure to the town of Belfast an annual expenditure of 60,000*l.*, now paid to strangers and foreigners."

There is at the present time an active movement in Belfast with respect to ornamental design. The production of specimens for the Exhibition of 1851 is one stimulus, and French workwomen have been engaged, not to supersede, but to instruct the native embroiderers of muslin.'

DETONATION is a chemical term employed to express combination or decomposition which occurs with noise and frequently with combustion. It occurs when oxygen and hydrogen, in certain proportions, are fired; when hydrogen and chlorine are heated by the sun's rays; when certain salts and oxides are struck or rubbed; and in some other cases.

DEVONPORT DOCK YARD. [PLYMOUTH.]

DEVONSHIRE. This fine county is rich in minerals available in the manufacturing arts. Slate rocks are very predominant. These rocks are quarried for roofing-slates: they are metalliferous, affording iron-stone, and veins of tin, copper, and lead: the veins or lodes which yield tin or copper, run, as in Cornwall, from N.E. to S.W. (approaching more or less to E. and W.), and those which afford lead run nearly at right angles to these. The strata in the mining field about Tavistock which yields tin, copper, lead, and manganese, are traversed by porphyritic (elvan) beds, bearing nearly east and west. A few lead and copper mines are wrought in North Devon: the lead is combined with silver. The limestone is quarried for building and burnt for manure: beautifully veined marble is worked in different places. Imperfect coal or lignite, called Bovey coal, occurs at Bovey Heathfield, on the right or south west bank of the West Teign or Bovey river in a plain where the strata of it rise to the surface. It lies in parallel seams from four to sixteen feet thick, at six or eight feet distance from each other, to the depth of sixty feet, and exhibits a gradation from the most perfect ligneous texture to a substance nearly approaching the character of pit coal. Potters' clay and pipe clay are found in the same neighbourhood. The Bovey coal is used for fuel in the potteries on Bovey heath, and by the poorer people of the neighbourhood: but its difficult and imperfect combustion, and fetid gas, render it unfit for domestic use. The Dartmoor granite is remarkable for the size of the felspar crystals which it contains: it is much valued for its durability, fineness of texture, and the size of the blocks: it is quarried and exported to a considerable extent, especially to London. It is metalliferous; containing veins of tin, even the rock itself being sometimes impregnated with this metal.

Grass land being far more abundant in Devonshire than arable, butter, cheese, and live stock may be considered as the chief agricultural produce for exportation. The clouted or clotted cream of Devonshire is a well-known delicacy; it is made by heating the milk on the hearth, or by means of a stove, to a degree a little below the boiling point, when the clouted cream ries to the top like a thick scum, and is taken off when cooled. This cream being merely stirred briskly with the hand or a stick, is converted into butter. The chief beverage of the Devonshire people is cider, which is here superior to any other in England. The soil on the slopes of the hills is peculiarly adapted to the growth of fruit trees, especially on a loose rocky bottom, where the roots may insinuate themselves and find moisture at all times. The wood grown in Devonshire is chiefly oak, but beech, ash, and elder are interspersed, according to the soil and situation.

A few towns are briefly noticed in separate articles; such as EXETER, CREDITON, HONITON, &c. We may here state that at Prince

Town, on Dartmoor, is a building which was formerly a prison, but which has lately been leased to a company who were engaged in extracting naptha from peat. Considerable interest is just now attached to this place from its being the field of an important experiment on the application of convict labour. In the autumn of 1850, a number of convicts were sent down here to be employed in the reclamation of a portion of the moor and other useful works. The prison is of such extent, and so well constructed, as to afford abundance of room, security, and facility of supervision, and the situation, though bleak and dreary, is very healthy, while it is sufficiently removed from any populous neighbourhood, thus permitting the experiment to be made under very favourable conditions. At present the number of convicts at Dartmoor is limited, but it is understood that it will be increased if the experiment succeeds.

Mining, quarrying, and lace-making are the chief industrial pursuits of Devonshire. Specimens from many of the chief towns will be displayed at the Great Exhibition.

DEWSBURY is one of the busy manufacturing towns of the West Riding district. Many extensive establishments are here in operation for the production of woollen fabrics chiefly of the heavy and useful kinds, such as blankets, carpets, and inferior descriptions of woollen cloth. There are also worsted yarn manufactories, and wool carding establishments; and wool-stapling, iron-founding, tanning, malting, and nail-making are extensively carried on. Several corn mills and lime-works are in the neighbourhood.

DEXTRINE, is a modification of starch procured by boiling common starch in dilute sulphuric acid and also in some other acids: by this treatment the starch soon loses its consistence and becomes thin and limpid, being converted into dextrine. When the ebullition is continued after the formation of the dextrine, this substance is converted into grape sugar, and this effect is produced with great readiness.

DIAGONAL SCALE. Equidistant parallel lines cut all lines drawn across them into equal parts. Consequently a set of equidistant parallels laid down upon a ruler, with oblique lines of various lengths drawn across them, give with the compasses the means of immediately taking off various proportions of those lines. The common diagonal scale is so formed as to facilitate the laying down of the hundredths of units in a scale of equal parts; and when well made it will shew $\frac{1}{100}$th of an inch with tolerable accuracy.

DIAMOND. This crystalline gem, on account of its high lustre and extreme hardness has always been regarded as the most valuable of the precious stones. The diamond usually occurs in imbedded octahedral crystals in alluvial ground, in the East Indies, Brazil, and the Ural mountains. It is commonly colourless or grayish, but sometimes green, yellow, red, brown, blue, and black: the two last-mentioned colours are the rarest. Its lustre is adamantine; refraction single; transparent, but sometimes rendered opaque by foreign matter. It is harder than any other substance, and can be cut or worn down only by rubbing one diamond against another; and it is polished by the friction of portions of the gem itself reduced to powder. It is broken without difficulty. The specific gravity of the diamond is 3.52. When rubbed, it phosphorises and becomes positively electrical. When heated, without the contact of air, it suffers no change; but, if ignited in contact with it, it is totally converted into carbonic acid gas.

For ornamental purposes diamonds are cut into two shapes, namely, *rose diamonds* and *brilliants*. The weight and consequently the value of diamonds is estimated in carats, each of which is equal to 3.166 grains.

It was conjectured by Newton that the diamond is a combustible body; but the proof of its being absolute carbon in a crystalline form was developed by slow degrees by the Florentine Academicians in the seventeenth century, by Lavoisier a century later, and by many chemists in the present century.

The pencil diamond used in cutting glass is a small fractured piece of diamond. The part of the diamond used is of a trapezoidal shape, weighing about the sixtieth part of a carat, and is set in a wooden handle.

The diamond-mines of Cuddapah in the East Indies, near Madras, instructively shew the mode in which these gems are procured. These mines have, it is said, been worked for several hundred years with various success. The places in which diamonds have hitherto been found consist either of alluvial soil or of rocks of the latest formation. The mines are pits of small depth. The diamonds are not scattered through the whole of the mine from the surface to the greatest depth, but occur in beds always harder than the adjacent soil, and usually not exceeding one or two feet in thickness. Dr. Heyne, who carefully examined these mines, has given in his statistical tracts the following description of one: 'The uppermost, or superficial stratum, consists of sand or gravel, mixed with a small proportion of loam. Its thickness scarcely exceeds a foot and a half. Immediately under it is a bed of stiff blueish or black mud, similar to what are seen in places that have been inundated; it is about five feet thick, and contains no stones. The diamond bed comes next, and is easily distinguished from the incumbent bed by the great number of large rounded stones which it contains. It is about two feet or two and a half feet thick, and is composed of large round stones, pebbles, and gravel connected together by clay.' The contents of this bed are put into a cistern about eight feet square and three feet deep, when water is poured into it, which separates the clay and loamy particles, leaving the gravel and small stones at the bottom. These being removed are thinly spread upon a smooth surface, about twenty feet square, of hardened clay, and six or seven people examine the whole carefully several times. At first they pick out the large stones; at the second and subsequent examinations the smaller gravel is carefully turned over by hand, while they 'watch for the spark from the diamond, which invariably strikes the eye.'

In 1845 the public journals gave frequent extracts from Brazilian correspondence relating to the discovery of a new diamond mine in that country. The locality was the Assuara, a desert part of the province of Bahia. At this spot gold was found a few years earlier; and among the many hundreds who flocked to work the gold veins, some discovered the presence of diamonds. No sooner was the discovery made, than the gold was abandoned, and the more precious diamonds sought for; and the accounts seem to convey the information that the store of these gems was very large. One ship is said to have carried to Europe diamonds to the value of 100,000*l.*

The commercial value of diamonds is a very curious feature. In the first place they are estimated by weight. A weight called a *carat* (equal to rather more than three grains troy) is taken as an unit, and is divided into halves, quarters, eighths, and sixteenths, to give fractional parts. Then the quality and form of the diamond are examined, and a price per carat fixed from all these circumstances. The larger the diamond the greater is the price per carat given for it. Under five carats, the price varies from thirty shillings to thirty guineas per carat: but very large diamonds, like *chefs d'œuvre* among pictures, obtain a price limited only by the competition of the small number of persons able to purchase them. The Russian diamond, the Pitt diamond, and the Pigott diamond, are gems which have obtained notoriety on account of their large size and enormous value. The celebrated *Koh-i-noor*, or *Mountain of Light*, is an Indian diamond which has lately fallen into the hands of the English at Lahore, and has been brought to this country as the property of Queen Victoria. It weighed 900 carats when rough, but this is reduced to 279 by cutting and polishing. As to its value, guesses have varied from half a million to three millions and a half sterling: shewing how vague are all attempts to estimate such rarities. It is said that Her Majesty intends to deposit this gem at the Industrial Exhibition.

DIAPER, is a kind of linen or cotton cloth, upon the face of which a figured pattern is produced by a peculiar mode of weaving. Diapers are chiefly used for table linen, fine towels, &c.

In decorative painting the term *diapering* is sometimes applied to a small pattern introduced to diminish the appearance of baldness where a considerable space is covered with one colour.

DIASTASE, is a substance formed during germination. It is prepared by reducing freshly germinated barley into a pulp, with half its weight of water, and then pressing out the liquor strongly. It is afterwards treated repeatedly with alcohol, purified, and precipitated. The precipitate is at last dried in thin layers upon glass at a temperature between 104° and 122° Fahrenheit. Diastase is solid, white, not crystalline, soluble in water, but insoluble in alcohol unless it be weak. Common malt is stated in general not to contain more than 1-500th of its weight of diastase; one part of it is sufficient to convert 2000 parts of starch, thickened with water, into a mixture consisting of much dextrine and a little sugar.

DIDYMIUM is a metal recently discovered in cerite. Cerite eventually yields, by treatment with sulphuric acid, large red crystals, which are sulphite of didymium, from which, by treatment with potash and exposure to a red heat, the oxide of didymium is obtained in small lumps of a brown or blackish colour; the powder is light brown. It has no alkaline reaction, and is dissolved pretty readily even by dilute acids, and they yield salts of an amethystine red colour. By the blowpipe the oxide mixed with the salt of phosphorus becomes amethystine red with a tint of violet; when heated with carbonate of soda or platina foil, it melts into a grayish white mass. It does not appear to have been reduced to the metallic state.

DIE-SINKING. In the preparation of coined money and of medals the most important feature is the engraving of the 'die' which is to form the stamp. The piece of steel is prepared with the utmost care, and is brought to a soft state when about to be submitted to the hands of the engraver. By the aid of small, fine, hardened steel tools, the engraver cuts away the steel until he has produced, in cavity or 'intaglio,' an exact reverse of the design for the medal or coin. The steel, in a soft state while being engraved, requires hardening before being applied to use. When further prepared so as to be rendered more durable, it obtains the name of the *matrix*, and might be used in that state to stamp coins or medals; but as such a matrix is very costly, and might be spoiled by fracture, arrangements are made for producing multiplied copies of it. A small block of soft steel is by immense pressure, made to receive an impress, *in relief*, from this matrix; and from this second piece, which obtains the name of the *puncheon*, after being hardened and retouched by the graver, *dies* or duplications of the original matrix are produced. In the use of dies by means of the stamping-press, the number of blows required to transfer the device to a blank piece of metal depends upon the depth of the intaglio.

A method sometimes adopted of producing medals from a die by means of stamping upon metal which is in a semi-liquid instead of a cold and solid state has been already described [CLICHE' MEDALLIONS]; the method is called *en cliché*, and has been much practised in France.

DIEPPE is among the busiest of the seacoast towns of France. The population of the suburb of Pollet, to the east of the town, are all engaged in the herring, oyster, and cod fisheries. The quantity of herrings cured has in some years amounted to 36,000 barrels, and of mackerel to 12,000 barrels. There are sugar-refineries, rope-walks, paper-mills, and ship-building yards in the town. Fine linen, lace, and articles of ornament in bone, horn, shellwork, and ivory, are made. Wine, brandy, vinegar, salt, nails, iron, steel, millstones, colonial produce also enter into the commerce of the town. The coasting trade is active.

DIGESTION, in Chemistry, is the exposure of any substance to partial or total solution in a fluid, either at common temperatures or with a gentle heat, as in the preparation of tinctures. It is commonly performed in a glass matrass, which is half filled with the fluid, and covered with a piece of wet bladder at the mouth.

DIORA'MA is the name given to a mode of painting and scenic exhibition invented by two French artists, Daguerre and Bouton. The peculiar and almost magical effect of the diorama arises, in a considerable measure, from the contrivance employed in exhibiting the painting, which is viewed through a large aperture or proscenium. Beyond this opening the picture is placed at such a distance that the light is thrown upon it, at a proper angle, from the roof, which is glazed with ground glass, and cannot be seen by the spectator. The light may be diminished or increased at pleasure, and that either gradually or suddenly, so as to represent the change from ordinary daylight to sunshine, and from sunshine to cloudy weather, or to the obscurity of twilight; also the difference of atmospheric tone attending them. Some parts of the painting are transparent, and on them the light can occasionally be admitted from behind, thereby producing a brilliancy far exceeding that of the highest lights of a picture upon an opaque ground. The combination of transparent, semi-transparent, and opaque colouring, still further assisted by the power of varying both the effects and the degree of light and shade, renders the diorama the most perfect scenic representation of nature. The principle forms the basis of an attractive exhibition in the Regent's Park, London; but it is also capable of being applied to the embellishments of corridors, &c.

DISTEMPER, is an inferior kind of colouring, used as a cheap substitute for oil colours. It is composed of whitening mixed with size, to which the colouring is added to form the necessary tint. Coarser colours are used for distemper than are employed in oil-painting. Scene-painting and paper-staining are executed in distemper.

DISTILLATION is a chemical process for applying a regulated heat to fluid substances in covered vessels, in order to separate their more volatile constituents in vapour: and for condensing them immediately by cold into the liquid state. The distillation of aromatic waters was known to the Greeks and Romans, and to the Arabians from very remote times. Arnoldus de Villa Nova and Raymond Lully both noticed in the 13th century, a mode of producing intoxicating spirits by distillation. The alchemists of those days imagined that spirit derives its ardent qualities from the fire employed to heat the vessels.

The only substances employed in this country in the manufacture of ardent spirits upon the great scale (which is the chief example of distillation) are different kinds of corn, such as barley, rye, wheat, oats, buckwheat, and maize. Peas and beans also have been occasionally used in small quantity. The principles in these grains from which the spirits are indirectly produced are starch and a little sweet mucilage, which, by a peculiar process called *mashing*, are converted into a species of sugar. It is the sugar so formed which is the immediate generator of alcohol, by the process of fermentation. In mashing one or more kinds of corn, a greater or smaller proportion of malt is always mixed with the raw grain, and sometimes malt alone is used, as in the production of malt-whiskey.

The manufacture of ardent spirits consists of three distinct operations: first, mashing; second, fermentation; third, distillation.

Mashing.—Either malt alone, or malt mixed with other grain, and coarsely ground, is put into the mash-tun, along with a proper proportion of hot water, and the mixture is subjected to agitation by a mechanical revolving apparatus. The water is applied at a temperature varying from 145° to 165° Fahr. After two or three hours' agitation, the whole is left to repose for an hour and a half, and then the worts (as the liquor is called) are drawn off to about one-third the volume of water employed, the rest being entangled in a pasty state among the farina. About two-thirds of the first quantity of water is now let into the tun, but at a temperature somewhat higher, and the mashing motion is renewed for nearly half an hour. A second period of infusion or repose ensues, after which these second worts are drawn off. Both infusions must be cooled as quickly as possible down to about 75° Fahr.: this is usually effected by exposing the wort for some time in large shallow cisterns, called coolers, freely exposed to aerial currents; but the liquor is sometimes cooled by being passed through serpentine tubes surrounded with cold water, or by the agency of ventilators blowing over its surface in extensive cisterns only three or four inches deep. A third mashing is conducted with a fresh portion of water in order to extract the remaining saccharine matter from the grain.

The specific gravity of the first and second worts, when mixed, is about 1.060; and the liquor contains about 60 lbs. of saccharine extract per barrel of 36 gallons. The three mashings employ about 27 gallons of water to every bushel of ground meal.

Fermentation.—This consists in bringing the worts to a fermented state. The worts are drawn off into a fermenting vessel; and yeast or ferment is added, sufficient to decompose the sugar in the liquor. The process is commenced at a temperature between 60° and 70° which soon afterwards rises to 85° or 90°. The first appearance of fermentation shows itself by a ring of froth round the edge of the vat usually within an hour after the addition of the yeast; and in the course of five hours the extrication of carbonic acid from the particles throughout the whole body of the liquor causes frothy bubbles to cover its entire surface. The yeasty froth begins to subside in about 36 hours, and, when the attenuation gets more advanced, the greater part of it falls to the bottom on account of its density relatively to the subjacent fluid. In from forty-eight to sixty hours the liquor begins to grow clear, and becomes comparatively tranquil. The liquor is stirred up occasionally during the fermentation, and the vessel is kept mostly closed after the first violence of the action. The specific gravity of the liquor diminishes as the process advances; the fermentation converts the sugar into alcohol or spirit; and, as the alcohol is lighter than water, it diminishes the specific gravity of the whole. The liquor itself is now called *wash*. 100 gallons of this wash contain about 12 gallons of proof spirit; if the whole of the sugar were decomposed (which it never is in practice), the produce of spirit would be greater. In the great distilleries, where the quantity of liquor operated on at once is very large, the duration of the fermenting process is longer than that above named.

Distillation.—Great distilleries are usually mounted with two stills, a larger and a smaller. The former is the *wash* still, and serves to distil from the fermented worts a weak crude spirit called *low-wines;* the latter is the *low-wine* still, and rectifies by a second process the product of the first distillation. In these successive distillations a quantity of fetid oil, derived from the corn, comes over along with the first and last portions received, and constitutes by its combination what is styled the strong and weak *faints*. These milky faints are carefully separated from the limpid spirit, by turning them as they begin to flow from the still into distinct channels, which lead to separate *receivers*. From these receivers the various qualities of spirit, low wines, and faints are, for the purpose of redistillation, pumped up into charging backs, from which they are run in guaged quantities into the low-wine and spirit stills.

The distilling apparatus, in one of the large establishments near London, is thus arranged. The wash is conveyed through pipes from the fermenting vessel to the wash-charger, which is a closed iron cistern, capable of containing 30,000 gallons. From this vessel the wash flows into the wash-still, a copper vessel holding 20,000 gallons; it is heated by a fire beneath, and is terminated at the top by a cover, which gradually decreases in diameter, and at length joins the worm, in another vessel. The wash is made to boil: and as alcohol boils and passes off in vapour at a temperature of 180°

Fahr., while water requires a temperature of 212°, the heating is so managed as never to reach 212°; and the alcohol vapour passes off with only a small portion of water vapour: if the process were perfectly conducted, there would be no water pass off with the spirit; but in practice there always is a small quantity, and to this extent the spirit is weakened by the mixture. The alcohol-vapour passes off into the worm, which is a copper tube curved spirally round the inside of a vessel thirty feet high, called the worm-tub: the tube is two feet in diameter at the upper part of the vessel, and diminishes down to two inches near the bottom. The worm-tub is filled with constantly flowing cold water, which keeps the copper worm at such a low temperature that the vapour in the worm is condensed into a liquid. This liquid, forming the *low-wines*, flows out of the narrow end of the worm into the low-wines receiver, from which it again flows into the spirit-still. Another distillation occurs, and sometimes a third, until so much of the water is driven off as to leave the spirit of a proper strength. Standard or 'proof spirit' consists of one half absolute or pure alcohol and one half water: if a given bulk of distilled water weighs 13 ounces, an equal bulk of proof spirit will weigh exactly 12 ounces. This difference of specific gravity gives rise to the construction and use of the HYDROMETER. There are certain stages or degrees of strength, 'above' or 'below proof,' according to circumstances: thus, the strongest spirit produced by distillation is 70° above proof, spirit of wine is not less than 43° above proof, raw spirits sold by the distiller to the rectifier are at 25° and 11° above proof, gin is about 17° below proof. The rectifying, or giving a modified strength and a peculiar flavour to spirit, is effected in totally distinct establishments from those in which the spirit is produced from grain. Scotch and Irish *whiskey* are distilled spirit without artificial flavour. English *gin* is flavoured with juniper berries, sugar, and other substances.

A large revenue is derived from distilled spirits; and the revenue officers exercise a most rigorous supervision over all the operations of a distillery.

The total number of proof gallons of spirits distilled and charged with excise duty, in 1849, was as follow:—

England	..	5,318,526 gallons
Scotland	..	10,444,709 „
Ireland	..	8,117,844 „
		23,881,079 gallons.

In looking at these numbers, we cannot fail to be struck with the circumstance that Ireland, with half the number of inhabitants, manufactures 50 per cent. more spirit than England: and (more striking still) that Scotland, with one-fifth of the population, manufactures twice as much spirit as England.

The Excise duty (7*s.* 10*d.* per gallon in England, 3*s.* 8*d.* in Scotland, and 2*s.* 8*d.* in Ireland) realised 4,847,217*l.* in 1849.

A few additional details respecting distilled spirits will be found under BRANDY, RUM, &c.

DIVING BELL. Much ingenuity has been devoted from an early period to the contrivance of apparatus for enabling men to descend beneath the surface of water, to a greater depth, for a longer space of time, and with less exertion and danger, than is possible by the unassisted powers of the body. Machines which in some degree included the principle of the Diving-Bell were suggested, contrived, and sometimes used for the purpose of obtaining property sunk in the sea or in rivers. At length, in the 16th century, the Diving Bell itself was invented and used; and Halley, in No. 349 of the 'Philosophical Transactions,' describes its defects, and suggests a remedy for them. In its simplest form the diving bell is a strong heavy vessel of wood or metal, made perfectly air and water tight at the top and sides, but open at the bottom. If such a vessel be gradually lowered into the water, in a perfectly horizontal position, the air which it contains cannot escape, and therefore the vessel cannot become full of water. Where the diving-bell is used for descending to a very small depth, as the pressure of the water is small, it will not rise in the bell to a sufficient height to be inconvenient; but at the depth of thirty-three feet the pressure is so great as to compress the air into one half its original volume, so that the bell will become half full of water; and at a greater depth the air will be still more compressed, and the water will rise proportionately higher in the bell. The unpleasant pressure of the condensed air on the ear, the difficulty of breathing, and the confinement of space within the bell, have all led to various improvements, by Dr. Halley and others.

The diving-bell used by Dr. Halley was of wood, in the form of a truncated cone, five feet in diameter at the bottom, and three feet at the top, and containing about sixty cubic feet. This was coated with lead, and so weighted about the lower part that it would sink while empty, and would always remain in its proper position; that is, with the large open end downwards, having its rim parallel with the horizon. In the top of the bell was a very strong glass window, and a cock, by opening which the foul air might be allowed to escape.

About a yard below the mouth of the bell was suspended a stage, so weighted that it might hang steadily. The apparatus for conveying air to the diving-bell consisted of two barrels, holding thirty-six gallons each, weighted with lead to make them sink readily. Each of these had an open bung-hole in the lower end, to allow water to enter during their descent, so as to condense the air; there was also a hole in the upper end of each, to which was fitted an air-tight leathern hose, long enough to fall below the bottom of the barrel, and having its loose end so weighted that it would fall naturally into that position. When the open end of the hose was turned up by the attendant, so as to be above the level of the water in the barrels, the air rushed out with great force into the bell, the barrels becoming at the same time full of water. By sending down these air-barrels in rapid succession, the air in the diving-bell was kept in so pure a state that five persons remained in it, at a depth of nine or ten fathoms, for more than an hour and a half at a time, without injurious consequences. When the sea was clear, and especially when the sun shone, sufficient light was transmitted to allow a person in the bell to write or read; and when the sea was troubled and thick, which occasioned the bell to be as dark as night, a candle was burnt in it. Halley sometimes sent up orders with the empty barrels, writing them with an iron pen on plates of lead.

The credit of having been the first to apply the diving-bell in aid of civil engineering operations is usually attributed to Smeaton, who used it in 1779 in repairing the foundations of Hexham Bridge. The bell used on this occasion was an oblong box of wood, four feet high, two wide, and three and a half long; and it was supplied with air by a pump fixed on the top. The river being shallow, the bell was not covered with water. In 1788 the diving-bell was used in a much more important work, Ramsgate harbour, by the same engineer. The depth here being considerable, an apparatus was employed for sending in a supply of air through a flexible pipe, by means of a forcing-pump. The bell used was of cast-iron, similar in form to that at Hexham, but four feet and a half high, four and a half long, and three wide. Its weight was 50 cwts., and the thickness was so adjusted that it would, without the addition of any weights, sink in the proper position. In levelling foundations under water by this machine the surface of the water at the bottom of the bell formed a convenient and unerring level to work to; and in this, as well as in the subsequent operation of building, every necessary motion was given to the bell by the tackle by which it was suspended; signals being made from below by striking one, two, three, or more blows upon the side of the bell with a hammer.

Since the time of Smeaton the diving-bell has been frequently, and with great advantage, employed in submarine works; sometimes in situations in which it would have been impossible to construct a coffer-dam, or to perform the required operations by any other means. The diving bells used in such works are usually formed on the model of that made for the works of Ramsgate Harbour; but the mode of suspension differs according to circumstances. The bell may be suspended over the side or end of a vessel; or through an opening in the centre of a barge; or from frame-work resting upon two barges, placed parallel with each other, but at such a distance apart as to allow the bell to descend between them; or from a scaffolding supported by piles. Of the use of this important machine in recovering property from wrecks, the operations upon that of the Royal George afford a familiar example. Smeaton's method of supplying air to the bell is that most commonly employed; but that of Halley may, in some cases, have the advantage.

One of the largest diving-bells ever constructed is that at the Polytechnic Institution. This machine is made of cast-iron, and weighs three tons. It has twelve glazed openings, six at the sides and six at the top: the glass being half an inch thick. It is 5 feet high, 4 feet 8 inches diameter at the bottom, and from 1½ to 2½ inches thick. Air is supplied to the bell by two air-pumps, with 8 inch barrels.
